Bridging Divides Between Environmental Stewardship and Economic Development

# Abstract Book

SETAC North America 39th Annual Meeting

## Table of Contents

### Platform Abstracts

Monday ............................................. 5
Tuesday ........................................... 54
Wednesday .................................... 101
Thursday ....................................... 150

### Poster Abstracts

Monday (MP) ................................. 199
Tuesday (TP) ................................. 268
Wednesday (WP) ........................... 337
Thursday (RP) ............................... 407
Thursday Poster Corner (PC).......... 451

### Indices

Author Index ................................. 457
Affiliation Index ............................ 475
Keyword Index ............................... 482
Session Index ................................ 486

This book comprises the abstracts of the presentations for the platform and poster sessions of the Society of Environmental Toxicology and Chemistry (SETAC) North America 39th Annual Meeting, conducted at the Sacramento Convention Center from 4–8 November 2018 in Sacramento, California. The abstracts are reproduced as accepted by the Scientific Program Committee and appear in numerical order.

In each abstract, the presenting author's name is underlined. The author index cross-references the corresponding abstract numbers. Affiliation, session and keyword indices are also included.

International Standard Serial Number 1087-8939

# About SETAC

The Society of Environmental Toxicology and Chemistry (SETAC), with offices in North America and Europe, is a non-profit, professional society established to provide a forum for individuals and institutions engaged in the study, analysis and solution of environmental problems, the management and regulation of natural resources, environmental education, and research and development.

Specific goals of the society are:

- Promote research, education and training in the environmental sciences
- Promote the systematic application of all relevant scientific disciplines to the evaluation of chemical hazards
- Participate in the scientific interpretation of issues concerned with hazard assessment and risk analysis
- Support the development of ecologically acceptable practices and principles
- Provide a forum (meetings and publications) for communication among professionals in government, business, academia and other segments of society involved in the use, protection and management of our environment

These goals are pursued through the conduct of numerous activities, which include:

- Conduct meetings with study and workshop sessions, platform and poster presentations, and achievement and merit awards
- Publish scientific journals, a newsletter and special technical publications
- Provide funds for education and training through the SETAC Scholarship/Fellowship Program
- Organize and sponsor chapters and branches to provide a forum for the presentation of scientific data and for the interchange and study of information about local and regional concerns
- Provide advice and counsel to technical and nontechnical persons through a number of standing and ad hoc committees

SETAC membership currently comprises about 5,400 individuals from government, academia, business and nongovernmental organizations with backgrounds in chemistry, toxicology, biology, ecology, atmospheric sciences, health sciences, earth sciences, environmental engineering, hazard and risk assessment, and life cycle assessment.

If you have training in these or related disciplines and are engaged in the study, use or management of environmental resources, SETAC can fulfill your professional affiliation needs.

All members receive the SETAC Globe newsletter highlighting environmental topics and SETAC activities, reduced fees for meetings and discounts on SETAC books. All members receive online access to *Environmental Toxicology and Chemistry* (ET&C) and *Integrated Environmental Assessment and Management* (IEAM), the peer-reviewed journals of the society. Members may hold office and, with the Emeritus Members, constitute the voting membership.

If you desire further information, contact the Pensacola office if you are in Latin America, Asia/Pacific or North America, or the Brussels office if you are in Europe or Africa.

# Fate of Organic Contaminants in Aquatic Invertebrates and Their Environments – Measurement, Modeling and Risk Management

**1 Using benthic invertebrate life history data to improve bioaccumulation predictions for a contaminated Northeast estuary**

*B.G. Church, S. Replinger, J. Toll, M. Johns, L. Saban, Windward Environmental LLC*

Benthic invertebrates as a group have incredibly diverse forms and life histories, but they are often treated as a homogenous accumulator of sediment contamination. Given the relative importance of benthic invertebrates as a vector for chemical transfer to higher trophic levels, it may be beneficial to more accurately characterize benthic invertebrates when modeling bioaccumulation. Life history information, such as diverse feeding strategies and expected depth of sediment exposure (i.e., feeding depth), was incorporated when developing a food web model for a Northeast estuary. This better characterization of benthic invertebrates has improved model calibration and confidence in predicted fish tissue concentrations. Although regional data was used for this study, the collection of site-specific data is recommended for future work to reduce uncertainty and further improve the model.

**2 Modeling Bioconcentration of Organic Pollutants in Amphipods and Midges**

*D. Kuo, City University of Hong Kong / Architecture and Civil Engineering; C.C. Chen, City University of Hong Kong*

Amphipods and midges are important players in aquatic ecosystems. They have been widely used as test organisms in the ecotoxicological studies of potential contaminants including bioaccumulation potentials. With increasing shift towards non-sentient organisms as focus of experimental studies and the need for shorter experiments, amphipods and midges are ideal laboratory invertebrates for ecotoxicological studies and risk assessment. This study aims at developing bioconcentration models for amphipods and midges based on the toxicokinetics of uptake and removal processes and polyparameter-based linear free energy relationships (pp-LFERs). Bioconcentration and toxicokinetic data were gathered from primary bioaccumulation literature and reviewed following a 7-stage data quality assessment protocol. A total of 45 and 161 bioconcentration factors (BCFs) were collected for 6 amphipod and 21 midge species, respectively, covering 83 organic compounds with log $K_{OW}$ ranging from 0.57 to 7.62. The resulting BCF models generally performed well, with RMSE of 0.68 and 0.67 for amphipod and midge, respectively. For short-duration uptake experiments (i.e., £ 7d), BCFs measured from radioactivity analysis appear consistent with those derived with analysis of parent chemicals. The limitations of the developed models point to three immediate needs: build up high-quality experimental $k_M$ values for representative invertebrate species, explore the potential role of exoskeleton in chemical binding, examine the bioaccumulation of ionizable organic contaminants, and standardize experimental procedure for different invertebrates.

**3 What if Bioaccumulation is Concentration Dependent? A Meta-Analysis on Invertebrates Data**

*D. Kuo, City University of Hong Kong / Architecture and Civil Engineering*

Currently, bioaccumulation potential is measured and expressed with different bioaccumulation metrics such as bioconcentration factor (BCF) and biota-soil/sediment accumulation factor (BSAF). The underlying key assumption of these factors is that bioaccumulation does not vary with exposure concentration or chemical activity. Standard bioaccumulation experiments are often conducted in laboratory at concentrations that are analytically convenient rather than environmentally realistic, with the laboratory exposure levels typically higher than field conditions. It is thus critical that the concentration independent assumption is valid. This study examine this assumption by conducting a meta-analysis of bioaccumulation data of organic pollutants in invertebrates across different exposure media including soil, sediment, and aqueous solution. Over 100 chemical-medium cases were found and retrieved from primary experimental studies. Existing evidence suggest that standard bioaccumulation factors tend to decrease with increasing exposure concentration for both polar and hydrophobic organic compounds. If the observed concentration trend is generally true, laboratory generated bioaccumulation factors may be underestimating the bioaccumulation potential of chemicals. Furthermore, new approach to describe bioaccumulation measurements may be needed. A number of plausible causes and reasons for the dependence are examined and discussed.

**4 Persistent organic pollutant monitoring in the Anacostia watershed using passive sampling and uptake in a freshwater mussel**

*N. Lombard, M. Bokare, University of Maryland, Baltimore County / Department of Chemical, Biochemical, and Environmental Engineering; R. Harrison, L.T. Yonkos, University of Maryland / Department of Environmental Science and Technology; F.E. Pinkney, U.S. Fish & Wildlife Service / Chesapeake Bay Field Office; U. Ghosh, University of Maryland Baltimore County / Chemical, Biochemical, and Environmental Engineering*

Located within a major urban environment, the Anacostia River continues to receive inputs of legacy pollutants from its watershed, resulting in accumulation in fish and the issuance of fish consumption advisories. Ongoing Remedial Investigation/Feasibility Study of the tidal Anacostia is aimed at identifying the extent and magnitude of contamination, assessing risks, and evaluating cleanup alternatives. Model predictions are also required to determine the concentration reductions in sediment needed to achieve target fish tissue concentration for the protection of human health. To address this aim, polychlorinated biphenyls (PCBs), polynuclear aromatic hydrocarbon (PAHs), and organochlorine (OC) pesticide concentrations in the water column and sediment porewater were monitored at several locations in the Anacostia River and major tributaries. A passive sampling approach was used and results were compared to quantify the dominant sources of pollution into the river. Caged mussels were concurrently deployed at the same tributary locations to measure in situ uptake in the tissue and determine if water concentrations are a good predictor for bioaccumulation at the lower trophic level of the food chain. Several organic pollutants in the Anacostia River water exceeded the EPA water quality criteria for the protection of human health. Our measurements indicate that some tributaries continue to serve as a source of the pollutants to the Anacostia River. Pollutant uptake was observed in mussel tissue over the three-month deployment period, in correlation with detected water concentrations. Partitioning-based bioconcentration models were tested and showed reasonable agreement within a factor of 2 to 10 between predicted and measured concentrations depending on the model tested. The overall results confirm that freely dissolved concentrations of persistent organic pollutants in the water column can be used to predict biouptake in filter-feeding benthic organisms. Results from this study are helping in the determination of the potential sources of contamination from tributaries into the River and developing better prediction of uptake in the aquatic food chain.

**5 Differential accumulation of select pharmaceuticals and contaminants of emerging concern in an effluent-dependent experimental stream mesocosm**

*S.R. Burket, B.W. Brooks, Baylor University / Department of Environmental Science*

Pharmaceuticals from wastewater treatment plant effluent are known to bioaccumulate in fish exposed to instream flows from urban ecosystems, particularly in arid and semi-arid regions; invertebrate bioaccumulation of these compounds is less defined. However, bivalves have been recently reported to accumulate some of the highest levels of antidepressants. For example, fish from an effluent dependent river accumulated up to 14 ± 4.6 µg/kg of the antidepressant sertraline compared to unionid mussels that accumulated sertraline to levels an order of magnitude higher (140±21 µg/

kg). Bioaccumulation differences among fish and bivalves have not been adequately studied and potentially result from different routes of exposure and disposition. *Corbicula fluminea*, an invasive freshwater bivalve, exhibits characteristics analogous to model organisms used for biomonitoring studies (e.g., broad distribution, rapid growth rate, high fecundity, ease of collection and transport, short acclimation periods). The goal of this study was to examine bioaccumulation and uptake of select target analytes by freshwater clams (*C. fluminea*), grazing fish (*Campostoma anomalum*), and periphyton during a replicated outdoor stream mesocosm study at the Baylor Experimental Aquatic Research facility. Municipal effluent, which was supplied from the Waco Metropolitan Area Regional Sewerage System, served as the stream flow source water. Organisms were sampled on study days 0, 1, 3, and 8. Target analytes were determined in whole tissue homogenates, source effluent and stream water by isotope dilution LC/MSMS. Following the 8-day study period, several target analytes were differentially accumulated between periphyton, fish and clams. For example, *C. fluminea* rapidly accumulated acetaminophen, carbamazepine, diphenhydramine, fluoxetine, and sertraline with maximum concentrations reaching low µg/kg levels. However, observed increases by study day 8 corresponded to increased target analyte concentrations in effluent source waters. Bioaccumulation dynamics of ionizable pharmaceuticals in *C. fluminea* and other bivalves (e.g., Unionids, estuarine and marine bivalves) requires additional study.

**6 Trait-based exposure assessment of Persistent Organic Pollutants in Antarctic Benthic Invertebrates**

*A. Krasnobaev, Wageningen University and Research / Toxicology; G. ten Dam, S. van Leeuwen, RIKILT – Wageningen University & Research; S.A. Morley, L.S. Peck, British Antarctic Survey, Natural Environment Research Council; N. van den Brink, Wageningen University / Dept of Toxicology*

Persistent Organic Pollutants (POPs) can be found in invertebrates inhabiting ecosystems all around the world, even in Antarctica. However, research on Antarctic marine benthic organisms is scarce due to difficulties in collection and analysis of samples. In this study we perform for the first time an exhaustive survey of levels of POPs in different species of marine invertebrates of the Western Antarctic Peninsula (WAP) with different feeding behavior. Multiple (n>10) samples of sea squirt (*Cnemidocarpa verrucosa),* limpet *(Nacella concinna),* sea urchin *(Sterechinus neumayeri),* sea cucumber *(Heterocucummis steineni) and* sea star *(Odontaster validus)* were collected by divers in Ryder Bay near the British Rothera research station during the austral summer of 2016/2017. Samples originated from 2 locations: in the direct vicinity of the station and further away in the bay, allowing the quantification of the potential release of POPs, related to local human activities. The presentation will contain detailed results on polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs) and Polybrominated diphenyl ethers (PBDEs). Preliminary outcomes indicate distinctive patterns between species and different POPs. Limpets appear to have higher concentrations than other species, contradicting the hypothesis that predatory species, like the sea star *(Odontaster validus),* contain highest concentrations of these compounds. In comparison to other studies (exclusively conducted in Eastern Antarctica), concentrations of PCBs (ΣPCBs 2-15 ng/g lipid weight) are relatively (10-1000 times) low. This might result from the unique atmospheric and hydrological characteristics of the WAP. Among the OCPs, legacy pesticides like ones of the DDT and chlordane groups were still detectable in the Antarctic invertebrates, but at relatively low concentrations. PBDE profile (ΣPBDEs 8-60 ng/g lipid weight) was dominated by the PBDE-209 although other congeners were also detectable. This demonstrates the major ability of these chemicals to accumulate in the Antarctic marine environment. The final outcomes of this study will provide new broad insights on the levels and characteristics of POPs in benthic invertebrates of WAP. They will also contribute to the incorporation of these species to the worldwide monitoring system of POPs, especially in the light of the WAP being considered as a region subjected to some of the world's highest climate change impacts.

**7 Quantifying Variability of Laboratory Bioaccumulation Tests**

*D.W. Moore, G.R. Lotufo, D. Farrar, A. Bednar, US Army Corps of Engineers ERDC / Enviromental Laboratory; M.K. Chanov, EA Engineering, Science, and Technology, Inc., PBC / Ecotoxicology; C.R. Warbritton, US Geological Survey / Columbia Environmental Research Center; M. Rempel-Hester, Aquatic Toxicology Support; S.W. Pickard, USACE, Buffalo District; J. Corbino, USACE, New Orleans District / Envrionmental Resources Specialist*

Bioaccumulation tests are a critical component of regulatory dredging evaluations. Standard bioaccumulation tests conducted in accordance with procedures outlined in the Ocean Testing Manual (OTM) and the Inland Testing Manual (ITM) utilize *Macoma nasuta* (a clam), *Alitta virens* (a polychaete) for marine tests and the oligochaete *Lumbriculus variegatus* for freshwater tests. Tests are designed to detect statistical differences in tissue residues of dredged and reference sediment exposed test organisms. However simple statistical differences may not equate to biologically relevant differences, therefore it is important to understand the role of variability associated with test design (laboratory exposure and tissue chemistry) and provide guidance to ensure appropriate expenditure of resources for additional analysis only when biologically relevant differences have been established. While many labs have demonstrated capability to conduct bioaccumulation tests and many labs have demonstrated capability to quantify tissue residues, the interlaboratory variability associated with conducting exposures and quantifying resulting tissue residues in 28-day bioaccumulation tests has never been addressed. To quantify variability of laboratory bioaccumulation tests, the USACE-ERDC, the USGS-CERC and two commercial bioassay laboratories (EA and EcoAnalyst) participated in an interlaboratory evaluation. Marine (*M. nasuta* and *A. virens*) and freshwater (*L. variegatus*) species were exposed in standard 28-day bioaccumulation tests to a marine and freshwater sediment , respectively, contaminated with low levels of PCBs(1-2ppm total PCBs) and PAHs (2-5 ppm total PAHs). At test termination all participating labs provided resulting tissues to ERDC's lab for analysis to enable quantification of exposure variability. In a separate, parallel experiment, the ERDC conducted a second set of 28-day *M. nasuta* and *A. virens* bioaccumulation tests utilizing the same marine sediment and exposure conditions and provided splits of the resulting tissue composite to ERDC's in-house lab and three commercial analytical laboratories for purposes of quantifying analytical variability. Results of interlaboratory comparisons (exposure and analytical) will be presented and the implications for determining biologically relevant differences in 28-day bioaccumulation tests discussed.

**8 Placement of Dredged Sediments in Aquatic Ecosystems: Interpreting Contaminant Bioaccumulation**

*A.D. McQueen, G.R. Lotufo, B. Suedel, US Army Corps of Engineers / Environmental Laboratory; A. Lenox, S.W. Pickard, USACE, Buffalo District; D.W. Moore, USACE/ERDC/Environmental Laboratory; K. von Stackelberg, Harvard School of Public Health / Environmental Health*

The potential bioaccumulation of sediment-associated contaminants from navigation-dredged material remains a primary source of ecological concerns associated with aquatic placement. Bioaccumulation bioassays using infaunal organisms exposed to dredged material and reference sediment are used in evaluations to assess the potential for contaminant-related impacts. To aid in interpreting bioassay results, statistical inferences and numerous assessment factors are recognized by the USEPA/USACE Ocean Testing Manual (OTM) and Inland Testing Manual (ITM) guidelines; however, detailed information for applying these factors to inform ecological risks are lacking. The goal of this study was to provide detailed guidance for evaluating the biological significance of contaminant bioaccumulation. Comparisons of the magnitude of differences (MODs) of tissue residues is one of the stated assessment factors for which there are limited data. Topic areas considered in this study to offer evidence-based information for applying MODs included 1) bioassay coefficient of variance [CV]), 2) bioaccumulation case studies from three geographic regions within the USA, and 3) reported uncertainty factors relevant to bioaccumulation endpoints. Based on peer-reviewed data and dredged material evaluations, within-sample variability of tissue concentrations were relatively low among testing organisms for a number of commonly assessed constituents (e.g., PCBs, PAHs, metals, butyl tins). For example, within-sample CVs for total PCB (n=12 congeners) tissue concentrations (n=5 replicates) ranged from 5-49% for 28-d standardized bioassays using worms (*L. variegatus* and *A. virens*) and 5-15% for bivalves (*M. nasuta*). Hypothesis-based statistical comparisons ($p< 0.05$; $\alpha=0.05$) were generally able to detect statistically significant differences among tissue concentrations with relatively low MODs (< 2 fold difference) for a number of bioaccumulative contaminants of concern (e.g., PCBs, PAHs, metals, butyl tins) measured in standardized testing organisms (e.g., *M. nasuta, L. variegatus,* and *A. virens*). These results indicate the importance of defining the associated uncertainty for translating bioaccumulation results from the laboratory to the field. Results from this study will provide information and resources to aid in the application of the OTM and ITM assessment factors (e.g., MODs) to inform realistic predictions of biologically significant bioaccumulation.

## Advances in Sediment Quality Assessment for Regulation and Management

**9 Solid-Phase Microextraction Sampling for Quantifying Polycyclic Aromatic Hydrocarbon Concentrations in Porewater to Monitor Sediment Cap Breakthrough**

*J.A. Williams, US Army Corps of Engineers / Environmental Engineering and Technology; A.V. Smith, Texas Tech University / Civil, Environmental, and Construction Engineering; B. Gardiner, US Army Corps Engineers / Engineering and Technology; R. Sanga, US Environmental Protection Agency; D.D. Reible, Texas Tech University / Civil and Environmental Engineering; M. Michalsen, US Army Engineer Research Development Center / Environmental Engineering & Technology Section*

Monitoring the integrity of sediment caps is critical to ensuring their long term functionality – isolating contaminants of concern and preventing contaminant migration through the cap and into the surrounding environment. *In situ* solid-phase microextraction (SPME) sediment porewater samplers can quantify upward or downward flux of contaminants through cap materials, thus serving as an "early warning" monitoring tool for cap breakthrough. At the Pacific Sound Resources (PSR) Superfund site located in Elliot Bay in Seattle, WA, in situ SPME samplers were used to monitor the potential migration of polycyclic aromatic hydrocarbons (PAHs) through the sediment cap placed over contaminated subtidal sediments. Concentrations of 18 PAHs were measured in sediment porewater under the cap, at various depths within the cap, and at the sediment-water interface. In 2011 and 2018, SPME samplers were deployed to a depth of 34 inches below the sediment surface for 14 days at 25 cap locations including several potential groundwater pathways. In 2011, PAHs were detected in nearly all depth intervals; however, no porewater results for any PAHs exceeded the Ambient Water Quality Standard (evaluation criteria used in the Second Five Year Review). PAH concentrations in the lower portions of the cap porewater were often very low (near the limits of detection), suggesting no upward PAH migration. However, for some PAHs (e.g. chrysene, fluoranthene, and pyrene), higher porewater concentrations were observed near the sediment cap surface, suggesting potential top-down migration from surface water or recent deposition. Data from the 2018 and 2011 SPME deployments will be compared to identify cap changes over time. The PSR case study illustrates how polymeric porewater samplers can directly support remedy decision making by assessing through-cap contaminant migration and cap functionality over time.

**10 Effect of Aging on Bioavailability of Legacy Contaminants in Sediment**

*J. Gan, A.R. Taylor, University of California, Riverside / Environmental Sciences; J. Wang, University of California Riverside; D. Schlenk, University of California, Riverside / Department of Environmental Sciences*

Hydrophobic legacy contaminants like dichlorodiphenyltrichloroethane (DDT) and polychlorinated biphenyls (PCBs) were banned almost half a century ago. While their residues still remain in many environmental compartments, they have undergone extensive aging and likely have much lower bioavailability as compared to fresh residues. However, risk assessment relies heavily on the use of total chemical concentration, rather than accounting for the age-diminished bioavailability, likely leading to overestimated risks. In this study, we used 24 h Tenax desorption to measure the potential bioaccessibility of DDTs and PCBs in two sediment cores taken from the Palos Verdes Shelf Superfund site in the Pacific Ocean. Bioaccessibility estimated by 24-h Tenax-aided desorption ($F_{24h}$) decreased in the order of DDD > DDE > DDT for DDT derivatives, and PCB 52 > PCB 70 > PCB 153 for PCB congeners, showing a negative correlation with their log $K_{ow}$. Due to the extensive aging, $F_{24h}$ values were < 20% of the total chemical concentration for most contaminants and < 5% for DDT, DDE and PCB 153, suggesting that aging greatly diminished their bioavailability. However, a quantitative relationship between $F_{24h}$ and sediment age along the vertical profile was not found, likely because the contaminant residues had undergone aging before their offsite transport and deposition onto the ocean floor. Bioaccumulation by marine polychaete *Nereis virens* was measured after the worms were exposed to the aged residues and the derived BSAF was compared to that from fresh-spiked sediment. BSAF was markedly smaller for the aged residues than for the fresh spiked compounds. As the use of man-made chemicals such as DDT and PCBs was discontinued many decades ago, the reduction in their bioavailability due to aging may be universal and should be taken into consideration to avoid overly conservative risk predictions or unnecessary mitigation interventions.

**11 Assessing trace element bioavailability in oxic and anoxic sediments through the use of a biomonitor**

*I. Proulx, GHD; L. Hare, INRS-ETE; B. Dupré, GHD*

Assessing the bioavailability of trace elements in sediments is important in ecological risk assessments designed to protect benthic communities and the predators that feed on them. The distribution, form and bioavailability of trace elements in sediments are largely influenced by the presence of oxygen. Chemical methods and models have been developed to assess trace element bioaccumulation and toxicity in oxic and anoxic sediments; however, such predictions tend to be approximate at best. A direct mean of estimating contaminant exposure is to measure trace elements in benthic animals themselves. Good candidates for estimating and comparing trace element bioavailability in oxic and anoxic sediments are larvae of the insect *Chironomus* (Chironomidae, Diptera) because larvae of some species are known to feed on oxic sediments while others on anoxic sediments. The possibility of using *Chironomus* larvae as sediment biomonitors was evaluated by determining if larvae take up the majority of their trace elements from oxic and anoxic sediments rather than from the overlying water that they pump through their tunnels in sediments for respiratory purposes. For this, we compared concentrations of trace elements in *Chironomus* larvae collected in lakes from Rouyn-Noranda (QC) and Sudbury (ON) to those in water (total and free ion) and in oxic and anoxic sediments from where they were collected. Overall, our analyses indicate that *Chironomus* larvae take up the majority of their trace elements from sediments; and thus, can be used to assess the bioavailability of trace elements in sediments. Given that *Chironomus* larvae can be used as sediment biomonitors, we evaluated if the bioavailability of trace elements differs between oxic and anoxic sediments in Rouyn-Noranda and Sudbury lakes. Comparisons of trace elements in larvae feeding on oxic sediments to those in larvae feeding on anoxic sediments collected from the same location indicate that the bioavailable concentration of arsenic, barium, cobalt, copper, manganese and nickel do not differ between oxic and anoxic sediments. However, they indicate that selenium is more bioavailable in anoxic sediments than in oxic sediments; whereas, cadmium and in some lakes zinc, are more bioavailable in oxic sediments than in anoxic sediments.

**12 Assessing avoidance and other behaviors in development of a sediment avoidance test for assessing remediation of contaminated sediments**

*R. Yeardley, USEPA / Land and Materials Management Division; W. Thoeny, Pegasus co USEPA Cincinnati; J.M. Lazorchak, USEPA / Office of Research and Development; T.P. Luxton, USEPA / Land and Materials Management Division; M. Mills, USEPA / National Risk Management Research Laboratory*

Since its development in 1996, versions of an earthworm avoidance test have seen wide and successful use in assessing contaminated soils, from both toxicological and ecological endpoints. Avoidance of contaminated sediments by aquatic macroinvertebrates has a similar potential to assess degree of contamination and success of methods for remediation of contaminated sediments (such as sediment amendments) at a range of sites (Superfund, Great Lakes AOCs, Mining sites). We assessed the use of the freshwater aquatic macroinvertebrates (*Chironomus dilutus* larvae, *Hyallela azteca*, and *Lumbriculus variegatus*) used in standard EPA methods for sediment toxicity and bioaccumulation (EPA Methods 100.1, 100.2, and 100.3) for use in sediment avoidance testing. Early testing has focused on metals-contaminated sediment. We found evidence of increased sensitivity vs. standard toxicity tests. Both *Hyallela* and *Lumbriculus* avoided metals-contaminated sediment at levels of contamination that caused weight loss but did not show statistically significant lethality in standard 7-day sediment toxicity tests with *Chironomus*. Experimental results, as well as available literature, show that behaviors other than avoidance of contaminants (feeding habits, predator avoidance, mating, phototactic responses to light) must be taken into account in choosing suitable test organisms, developing test procedures, and interpreting results. For instance, *Hyalella* and *Lumbriculus* both showed some evidence of negative phototaxis in absence of substrate. However, with introduction of other physical factors and associated behaviors, the picture changes. With sediment present in the test chambers *Hyalella* seemed to show a positive phototaxis while *Lumbriculus* showed no preference for light or dark sides of the chambers. Our observations indicate that lack of sufficient movement as well as tube-building behavior of *Chironomus* larvae make this organism less than ideal for avoidance tests. Choice of reference sediment is discussed. Though these tests are relatively short (24-48 hours), with a large enough difference in organic content between test and reference sediments, feeding behavior may come into play and cause preference for the sediment with higher organic content and make interpretation of results more difficult.

**13 Refinement of in-situ Toxicity Identification Evaluation (iTIE) System for Assessing Contaminated Sediments, Remediation, and Source Identification**

*G. Burton, University of Michigan / School for Environment and Sustainability; M. Hudson, University of Michigan / School of Natural Resources and Environment; M. Colvin, SPAWAR Systems Center Pacific / Energy and Environmental Sustainability; J.M. Daley, LimnoTech, Inc. / School of Natural Resources and Environment; E. Verhamme, T. Dekker, LimnoTech; G.H. Rosen, SPAWAR Systems Center / Energy and Environmental Sustainability; E.C. Cervi, University of Michigan / SEAS*

It is difficult to assess the toxicity of a single stressor and establish a strong stressor–causality link when multiple stressors coexist. The USEPA's Toxicity identification evaluation (TIE) methodology uses a series of chemical and physical manipulations to fractionate compounds within a matrix and systematically identify potential toxicants. The TIE provides useful information; but, lacks ecological realism as it is subject to laboratory-related artifacts. The in situ TIE (iTIE) technology is a biological-chemical fractionation system that systematically identifies causes of toxicity. The iTIE has undergone a number of iterations to increase the robustness and reliability of the novel technology. The 2018 prototype consists of a rectangular unit capable of housing an array of iTIE units. Each unit is equipped with an organism exposure chamber, a smaller chamber filled with a resin absorbent to fractionate porewater, surface water or effluent passing through the organism chamber, and a connection to a water collection container. A secondary containment unit is used to house the electronic controller along with other components which connects to the primary iTIE housing array. The iTIE system was deployed to a depth of 3 meters and evaluated in streams and marine harbors. The system assisted weight-of-evidence studies to assess stream impairments, wastewater effluents, porewaters and groundwater-surface water interactions using multiple species. Chemical analyses of water and iTIE chemical sorptive resins confirmed lethal to sublethal responses. This latest iTIE prototype provides a robust technology that improves stressor-causality linkages.

**14 Identifying key toxicants in sediment using an integrated method of TIE and EDA: A case study in Guangzhou, China**

*J. You, Jinan University / School of Environment; H. Li, Jinan University; F. Cheng, Jinan University / School of Environment*

Prioritizing toxicants is of a great challenge in ecological risk assessment for sediments in urban waterways which are seriously polluted by multiple stressors. Identifying key toxicants is an indispensable step in prioritizing toxicants concerning environmental risk assessment, management and policy decision. Two approaches, namely toxicity identification evaluation (TIE) and effect-directed analysis (EDA) have been developed to diagnose the causes of sediment toxicity. Conventional sediment TIEs take the advantage of environmental relevance by using whole organism bioassays yet suffer from lack of effective methods for pinpointing main contributors from a universe of organic chemicals. Alternatively, EDA is a powerful tool in identifying causes of sediment toxicity with sophisticated fractionation and chemical analysis methods, but it is usually short of environmental relevance due to the use of in-vitro bioassays and exhaustive solvent extraction. To better understand the cause of sediment toxicity in urban waterways in Guangzhou, China, an integrated method of TIE and EDA was developed. Whole-sediment TIE in combination with bioaccessibility-based extraction found that sediment mortality to the benthic invertebrate, *Chironomus dilutus* was caused by organics and metals jointly and organic pollutants contributed to the mortality for all samples. To better elucidate the roles of non-target organic contaminants in sediment toxicity in these sediments, EDA tests were performed with midge mortality and cell viability as the endpoints. To better understand the mode of action of the toxicants, four cell lines (HepG2, MCF-7, A549 and SH-SY5Y) were used to distinguish toxicants related to metabolism dysfunction, endocrine disruption, respiratory toxicity and neurotoxicity, respectively. All test sediment samples showed significant cell proliferation of SH-SY5Y cell line, but no effect on HepG2 and A549 cell lines. The toxicants were identified in the toxic fraction with GC-MS-MS after separating the extracts to 35 fractions using NPLC. The results were confirmed by midge toxicity testing. The proliferation of SH-SY5Y proliferation was partially explained by oxidative stress. In conclusion, an integrated method of TIE and EDA would provide an environmentally relevant and toxicant specific approach to effectively determine causality of sediment toxicity by combining the advantages of the two methods.

**15 Comparator Site Selection to Inform Screening-Level Causal Assessments**

*D. Gillett, R.D. Mazor, Southern California Coastal Water Research Project; A. Roseberry-Lincoln, J.M. Diamond, Tetra Tech, Inc.*

Sites in poor ecological condition often require causal assessment to determine appropriate follow-up steps. A key component of this process is to identify a series of ecologically similar sites that are used to assess potential stressors at the impaired site. comparator sites should: 1. be capable of supporting similar biota to the impaired site; 2. consist of sites from a similar environmental setting; 3. comprise a gradient of biotic condition; and 4. contain enough sites to assess variability. There are number of methods for selecting groups of comparator sites to be used in a causal assessment. In the present study, we compared the outputs of two similar, but distinct approaches that were applied across a large number of degraded stream sites in Southern California. One approach selects comparator sites based upon their natural environmental setting (e.g., slope, geology, elevation) and the other uses estimates of expected biological similarity (Bray-Curtis dissimilarity of modelled biotic assemblages). Both approaches were used to generate groups of comparator sites for 81 different stream-segments that have degraded benthic macroinvertebrate assemblages. The groups of comparator sites generated by each approach were evaluated against our comparator site suitability criteria to determine the performance of each approach. The groups of comparator sites identified by both approaches fared well against the four suitability criteria listed above, with greater than 80% success (i.e., comparator sites that passed any single criterion) by both methods in each criterion. The results of this study suggest that both methods – environmental similarity and expected biological dissimilarity – produced good groups of comparator sites in a quantitative, rapid, and conceptually transparent fashion at the scale needed in a large, complex monitoring and assessment program, with each method having subtle advantages for specific applications. The success of these methods in turn sets the groundwork for developing a novel screening-level approach to causal assessment that can be used to quickly diagnose stressors and prioritize problematic waterbodies for follow up from the appropriate regulatory and regulated agencies.

### 16 Stream Pollution Trends Program (SPoT): California Sediment Contaminant and Toxicity Monitoring Related to Land Use

*B.M. Phillips, B.S. Anderson, University of California Davis / Environmental Toxicology; J. Voorhees, Marine Pollution Studies Laboratory / Environmental Toxicology; K. Siegler, L. McCalla, S. Zamudio, R.S. Tjeerdema, University of California Davis / Environmental Toxicology*

The Stream Pollution Trends Program (SPoT) monitors the health of 100 California watersheds through measurements of sediment toxicity and contaminants. The focus of the program is trend monitoring based on land use, particularly developed, agricultural and open lands. Developed land area in California increased by 3.7% between 2001 and 2011, and the net increase in impervious surface was 8.8%. Among the developed land uses, developed open space decreased, but there were substantial increases in medium and high impact development. Increases in developed land have coincided with decreases in scrub, grasslands and agricultural lands. Since its inception in 2008, SPoT has identified significant increasing trends in current-use pesticides, heavy metals and the PBDE flame retardants in urban areas. Some individual pyrethroid pesticide concentrations are significantly increasing in all three land use areas, whereas individual metals such as copper are only increasing in open areas. Concentrations of legacy contaminants, such as DDT and PCBs are low at SPoT sites, but significantly decreasing trends are not discernable. Trends in toxicity, measured as survival of laboratory test organisms (the amphipod *Hyalella azteca*) in ambient sediment samples, have been decreasing in open areas, but are stable statewide with significant toxicity observed at approximately one in five sites. The highest incidence and magnitude of toxicity has been associated with urban land use and pyrethroid pesticides. SPoT recently expanded its analyte list to include the urban-use pesticide fipronil, and has added another test organism (the midge *Chironomus dilutus*) to assess potential impacts of this pesticide. Although concentrations of fipronil remain below toxicity thresholds, three years of paired monitoring with the two organisms at urban sites show a decrease in amphipod toxicity and an increase in midge toxicity. SPoT will continue to adapt to identify trends in emerging contaminants through the introduction of new analytes, toxicity test organisms and novel monitoring methods, such as bioanalytical tools and non-target analysis.

## Chemical, Biological and Instrumental Methods for Detecting Harmful Algae Blooms and Their Natural Toxins

### 17 Monitoring Approaches and Methods for Multiple HAB Toxins Across the Freshwater-Marine Continuum in Coastal California

*M. Howard, Southern California Coastal Water Research Project; R. Kudela, University of California Santa Cruz / Ocean Sciences; S. Theroux, Southern California Coastal Water Research Project; D. Caron, University of Southern California; K. Loftin, US Geological Survey / OGRL; M. Peacock, Northwest Indian College; A. Donovan, US Geological Survey; R. Fadness, California State Water Resources Control Board – North Coast Region; K. Hayashi, University of California Santa Cruz; Z.R. Laughrey, US Geological Survey; J. Smith, A. Tatters, University of Southern California*

The conventional focus of HAB monitoring programs has been to monitor and analyze toxins according to the waterbody type sampled, either as marine toxins or freshwater toxins, but not both. However, recent studies have shown that cyanotoxins have far reaching-effects downstream of their freshwater origin in brackish and marine waterbodies. These studies underscore the importance of inland waters as potential conduits for transfer of freshwater toxins to the marine environment, and highlight the importance of a comprehensive, multi-toxin (both marine toxins and cyanotoxins) approach to monitoring throughout the freshwater-marine continuum. There is a new recognition that management and mitigation of HABs needs to occur cohesively across waterbodies within freshwater, estuarine and marine environments due to hydrologic interconnections and toxin impacts downstream of bloom origins. As such, HAB monitoring approaches and methodologies have been developed specifically to address the challenges of comprehensively measuring all types of HABs across a variety of waterbodies. This presentation will focus on the combination of water sampling methodologies, both for toxins and HAB organisms, that have been developed to address this need and have been employed throughout coastal California in regional monitoring and specialized research studies. Passive sampling devices, specifically Solid Phase Adsorption Toxin Tracking (SPATT), have proven to be a critical method for HAB monitoring at the land-sea interface since SPATT provides time-integrated and multi-toxin measurements across all waterbody types. The combination of passive sampling with traditional grab sampling will be discussed, along with the importance of dissolved toxin measurements, often overlooked and under sampled in current ambient monitoring programs in CA. HAB organism identification methods can be accomplished through a combination of methods depending on the specific monitoring needs. The relative abundance index methodology uses microscopy and provides a rapid assessment of HAB genera/species, which can be used to inform event response and to determine the toxins analysis needs. Molecular methods, such as DNA sequencing, can provide more in-depth and quantitative HAB identification. Preliminary comparative studies of both relative abundance microscopy and DNA barcoding indicated a good agreement of broad community composition results.

### 18 Estimating Cyanotoxin Occurrence with Real-Time Water-Quality Data: Case Studies in Kansas and Ohio Lakes and Rivers

*J. Graham, G.M. Foster, D. Francy, T.J. Williams, US Geological Survey*

Toxins produced by cyanobacteria (cyanotoxins) are increasingly a global concern in waterbodies used for drinking water and recreation. Early notification of cyanotoxin occurrences would allow proactive, rather than reactive, management approaches to ensure public health protection. Water-quality data collected continuously and transmitted in near real-time provide a useful indicator of changing water-quality conditions that may affect drinking-water treatment processes and recreational use of waterbodies. Models developed using continuous water-quality data have shown promise as tools to estimate the probability of cyanotoxin occurrence and concentration. Model outputs can be delivered through a variety of platforms to provide timely and relevant public health information to water resource managers. Four case studies, representing seven study sites, conducted by the U.S. Geological Survey in cooperation with local and state partners, from lakes and rivers in Kansas and Ohio will be used to demonstrate the development, refinement, and implementation of water-quality indicators and models to estimate occurrence and concentration of the cyanotoxin microcystin. Logistic regression models to estimate probability of occurrence and/or linear regression models to estimate concentration were successfully developed at all study sites. Models and explanatory variables were site specific. Chlorophyll and phycocyanin fluorescence were included in models most often and streamflow, turbidity, pH, and dissolved oxygen also were useful indicators at some sites. In one case study (Cheney Reservoir, Kansas), models were initially developed in 2013 and have performed well over time. In contrast, in another case study (Kansas River, Kansas), models initially developed in 2016 did not perform well in subsequent years, likely because of flow-driven environmental conditions in this system. In three of the four case studies, water-quality tools have been used with other information to inform management decisions. A real-time model is being validated for a Lake Erie drinking-water intake site in 2018. These case studies demonstrate the strengths and limitations of near-real-time notification tools that indicate when water-quality conditions are changing rapidly or are likely to cause cyanobacteria-related events.

**19 Spatiotemporal variability of cyanobacteria and cyanotoxins, and the potential for sensor-derived recreational advisory status**

*G.M. Foster, J. Graham, US Geological Survey; T. Stiles, Kansas Department of Health and Environment; L.R. King, US Geological Survey*

Cyanobacteria and associated toxins in Milford Lake, Kansas, have been determined to be the cause of both human illnesses and animal deaths, and have had an economic impact on surrounding areas. The lake has been under recreational warnings because of high concentrations of the cyanotoxin microcystin every summer since 2011. Extreme spatiotemporal variability in cyanobacteria and microcystin in Milford Lake and other recreational waterbodies poses unique challenges to collecting representative samples for scientific study and public health protection. During the summers of 2015 through 2018, the U.S. Geological Survey, in collaboration with the Kansas Department of Health and Environment (KDHE), collected continuous data from a combination of time-lapse cameras and fluorescence sensors in Milford Lake. These data, along with water samples collected for laboratory analysis, were used to quantify the spatiotemporal variability of cyanobacteria and microcystin. The KDHE monitors cyanobacteria and microcystin in Kansas lakes and is responsible for issuing public health advisories and warnings when concentrations exceeded state-established guidance values. The main objective of this effort was to inform monitoring strategies for public health protection. Time-lapse camera data showed that near-shore accumulations of cyanobacteria can appear and disappear within minutes. Although cyanobacterial biomass and microcystin concentrations often varied by orders of magnitude between near-shore and off-shore locations, the shore-based sampling strategy employed by KDHE to issue public health advisories was consistently representative of the entire lake. During the summers of 2016 through 2018, surrogate microcystin models were developed and used to quantify spatiotemporal variability and evaluate near-real time estimates of microcystin concentrations for utility as a management tool. Exceedance of KDHE guidance values often changed from no advisory to watch and/or warning over the course of a day because of the variability in cyanobacterial biomass and microcystin concentrations caused by bloom development and dissipation. Continuous water-quality monitors may be useful in informing public health decisions in lakes with variable cyanobacterial bloom conditions. However, site-specific models need to be developed, and best practices for using continuous water-quality monitors to inform cyanobacterial bloom management strategies need to be established.

**20 Determination of multiple classes of cyanotoxins in water and fish tissue using liquid chromatography tandem mass spectrometry**

*S. Haddad, Baylor University / Environmental Science; R. Taylor, Baylor University / Department of Chemistry; L. Lovin, Baylor University / Environmental Science; K. Chambliss, Baylor University / Department of Chemistry and Biochemistry; B.W. Brooks, Baylor University / Department of Environmental Science*

Current analytical methods for cyanotoxins typically detect discrete classes of cyanotoxins in one matrix and rarely include saxitoxin, a select agent. Thus, a multi-toxin screening method for microcystins (MCs), nodularin (NOD), anatoxin-a (ANA), cylindrospermopsin (CLD), and saxitoxin (SAX) was developed to monitor target analytes in environmental water and fish tissue. Due to the broad range of cyanotoxin physiochemical properties, two separation techniques, hydrophilic interaction liquid chromatography (HILIC), corresponding toANA, CLD, and SAXand reverse phase liquid chromatography (RPLC), corresponding to MCs and NOD were paired to improve isolation and detection. Likewise, isolation of target analytes from water was achieved using the Waters Oasis HLB (RPLC method) and the Supelclean ENVI-carb (HILIC method). The large variation in $pK_a$and lipophilicity of cyanotoxins led to a systematic study of extraction behaviors using different solvent systems comprised of varying ratios of acetonitrile, nanopure water, and aqueous 0.1%formicacid to optimize extraction from fish tissue corresponding to the HILIC or RPLC methods. Further, commercially available isotopically labeled internal standards (IS) for microcystin-LA, LR, RR, and YR were used for the first time to correct for matrix effect and extraction bias of MCs. This protocol further evaluates the use of a zwitterionic HILIC analytical column to separate ANA, CLD, and SAX simultaneously, for the first time. Recoveries in water ranged from 53 – 98% and from 45 – 103% in fish tissue. Method LODs ranged from 4.0 to 80 pg (0.004-0.08 ng $mL^{-1}$), LOQs ranged from 10 to 280 pg (0.01-0.28 ng $mL^{-1}$), and MDLs ranged from 80 to 960 pg (0.08-0.96 ng $L^{-1}$) in water and 120 to 700 pg (0.12-0.70 mg $kg^{-1}$) in fish tissue.An ion suppression ranging from -22% to -77% was observed for MCs and NOD in water, with IS corrections showing improvement where ion suppression and enhancement ranged from -4.2% to +5.4%. Similar to water, ion suppression for fish tissue ranged from -26% to -58%, which was improved with IS correction, where relative values ranged from -17% to +17%. This method was subsequently used to screen for target analytes in water and fish from a caged fish study staged in a hypereutrophic impoundment during summer and winter. MC-LA and LR were detected in all water samples from both sampling periods, however no cyanotoxins were observed in fish tissue.

**21 High Frequency Monitoring of cyanoHABs Dynamics**

*J. Allen, USEPA / Office of Research and Development; J. Lu, ; J.W. Santo Domingo, USEPA / Cincinnati; A. Lindquist, USEPA ORD; H. Mash, USEPA / ORD / NRMRL; T. Sanan, USEPA / NRMRL / Water Supply and Water Research Division / Treatment Technologies Evaluation Branch; C.T. Nietch, USEPA / Water Supply and Water Resources Division; S. Guglielmi, Pegasus Technical Services Inc. / co USEPA Cincinnati; J. Shoemaker, USEPA / Office of Research and Development; D. Tettenhorst, USEPA / NERL; K. Daniels, USEPA / Water Supply and Water Resources Division; T. Neyer, Clermont County Ohio*

USEPA's Office of Research and Development has partnered with the Clermont County, OH Water Resources Department in an on-going study to assess HAB trends and develop monitoring tools and approaches. Lake Harsha, a multi-use reservoir and primary drinking water source in southwest OH, has experienced an increase in cyanoHAB frequency and intensity over the past several decades. The goal of this work is to develop relationships between HAB indicator measures and cyanotoxin occurrence which can provide time-relevant information regarding source water quality for DWTP operators and other public health stakeholders. In order to characterize the cyanobacterial population and both intracellular and extracellular cyanotoxin production, an intensive sampling regime was implemented beginning in 2015. High frequency (HF) monitoring (in-vivo fluorescence and physico-chemical parameters) was used to determine the timing and rate of discrete sampling of cyanotoxins (LC-MSMS analysis of select MC congeners and a total MC surrogate, cylindrospermopsin, and anatoxin-a, MC ELISA), molecular indicators, taxonomic enumeration, and nutrients, varying from biweekly, to daily collection during the observed bloom peak. Resulting data provide a time-series of the cyanobacterial population dynamic and greatest periods of cyanotoxin production. HF data coupled with cyanotoxin analyses demonstrate the utility of HF data for tracking the cyanoHAB status of the reservoir. It is also apparent that cyanotoxin concentrations may potentially be underestimated if cyanotoxin sampling is not coupled with bloom status. An overview of data and observations from 2015 to the present will be presented.

**22 Use of passive samplers for the detection of extra cellular algal toxins in stream mesocosms, lakes and streams**

*H. Mash, USEPA / ORD / NRMRL; D. Shea, NC State University; M. Howard, Southern California Coastal Water Research Project; R. Kudela, University of California Santa Cruz / Ocean Sciences; J. Allen, J.M. Lazorchak, USEPA / Office of Research and Development; T. Sanan, USEPA / NRMRL / Water Supply and Water Research Division / Treatment Technologies Evaluation Branch; C.T. Nietch, USEPA / Water Supply and Water Resources Division*

Freshwater Harmful Algal Blooms (HABS) occur frequently throughout the US and many parts of the world. Most of the emphasis on freshwater HABs has been on reservoirs and lakes with recreation and drinking water uses. However, there is mounting evidence that attached benthic cyanobacteria may be increasingly dominating the benthic periphyton community and contributing harmful toxins to streams and rivers. For the past 3 years the USEPA has been testing the consequence of nutrient addition into stream mesocosms. Macroinvertebrate and periphyton communities have been assessed using various measures for their responses to various concentrations of nitrates, phosphates and combination of nitrate/phosphates. At certain doses of these nutrients, cyanobacteria tend to dominate the benthic community. The USEPA and their collaborators have also been studying a HAB-impacted lake (Lake Harsha) for the past 7 years. Most HAB detection methods use discrete water sampling for toxin measurements and cyanobacteria identification. However, newer methods have been developed to detect toxins in California rivers using passive samplers called Solid Phase Adsorption Toxin Tracking (SPATT). A study conducted in China by North Carolina State University researchers has compared several different passive samplers in China, including SPATTs, Polar Organic Chemical Integrative Samplers (POCISs) and other novel Passive Sampler Devices (PSDs). The results indicate that Large Format non-selective PSDs (LF nsPSDs) performed better than other PSDs in recovering microcystins. The purpose of this study is to evaluate SPATTs and LF nsPSDs to determine their performance in determining extracellular algal toxins in both stream mesocosms and within Lake Harsha and its downstream habitats. PSDs were deployed at the end of 16 different stream mesocosms and in two influent mesocosms for a period of two weeks. Every two weeks during the mesocosm study, water samples were collected, PSDs retrieved and then replaced with fresh PSDs. A similar method was followed for PSDs in the lake at 2 locations and at 2 separate depths. Four stream locations were chosen below the outfall of the lake to determine the contribution of lake algal toxins to the downstream stream community. The results of this study will be presented comparing the 2 different types of PSDs and describing the pattern of algal toxins observed in each experimental unit.

**23 Detection of Free and Covalently Bound Microcystins in Sediment and Clam Samples from the San Francisco Estuary**

*M. Bolotaolo, University of California Davis; I. Gennity, B. Puschner, University of California, Davis / School of Veterinary Medicine; S.A. Lesmeister, State of California, Department of Water Resources / Division of Environmental Services; S. Teh, University of California Davis / School of Veterinary Medicine*

Microcystins, a class of hepatotoxins produced by a variety of cyanobacteria species, can significantly impact the health of both animal and human populations. Cyanobacterial blooms are predicted to become more severe worldwide due to rising surface water temperatures and increasing eutrophication of water bodies. Elevated water temperatures and increased UV exposure have also been found to promote growth of toxigenic species. Analytical techniques must allow for accurate quantification of microcystins in biological and environmental specimens to evaluate risk factors, yet this task is challenging as microcystins can become covalently bound to proteins. Thus, methods solely based on solvent extraction may lead to false negative results as they are unable to liberate bound microcystin residues. Here we developed a targeted GC-MS method in which microcystins are oxidized via the Lemieux reaction causing cleavage of the Adda amino acid moiety of microcystins, releasing the compound 3-methyl-2-methoxy-phenylbutric acid (MMPB), and allowing indirect detection and quantification of total microcystin concentrations. The limit of detection and limit of quantification was determined to be 10 ng/g and 50 ng/g, respectively. This method was then used to analyze sediment and clam samples collected from twelve sites in the San Francisco Estuary during May and October of 2017. Our results showed that 40% of the sediment samples were positive for microcystins with concentrations ranging from 16.3 – 151.0 ng/g. All the clam samples had microcystin concentrations below limit of detection. Microcystin positive soil samples were mainly found along the San Joaquin River, suggesting this water body being a potential source for microcystin exposure to the benthic community. This method allows sensitive detection of microcystins and reveals new information for environments at risk.

**24 A nontargeted LC-HRMS approach to correlating differences in HAB chemical 'fingerprints' with toxicity**

*R. Taylor, J.M. Bobbitt, Baylor University / Department of Chemistry and Biochemistry; B.N. Hill, Baylor University / Department of Environmental Science; A.S. Hering, Baylor University / Department of Statistical Sciences; B.W. Brooks, Baylor University / Department of Environmental Science; K. Chambliss, Baylor University / Department of Chemistry and Biochemistry*

Harmful algal blooms (HABs) are an increasing threat to global water supplies, affecting local economies, public health, and aquatic ecosystems. Their occurrence has historically been studied in estuaries, but HAB incidence in freshwater bodies continues to increase in frequency, duration, and magnitude because of environmental conditions promoted by climate change and urbanization. However, recent work has shown that known toxins fail to completely depict health threats of inland HABs, suggesting that additional compounds responsible for altering bloom toxicity still need to be identified. Traditional bottom-up approaches to toxin identification require time- and labor-intensive studies to systematically identify each component of a HAB mixture and then determine each one's toxicity. We have developed an alternative approach to toxin identification to alleviate the need to identify each component of the complex algal mixture. Instead, the entire chemical 'fingerprint' of algal culture filtrates was examined through nontargeted analysis, and changes in the LC-HRMS heatmap were correlated with changes in toxicity. Changes in the LC-HRMS heatmaps were visualized using relative difference plots which are plots comparing the intensities of a toxic/sample ion map to the intensities of a nontoxic/reference ion map. As a proof of concept, experiments were completed with spiked microcystin samples that contained intentional differences in their chemical 'fingerprint'. Compounds with concentrations changing the most between samples were successfully highlighted while compounds at the same concentration in both samples disappeared from the relative difference plots. *Prymnesium parvum* cultures expressing various levels of acute toxicity were then analyzed using this approach to quickly identify constituents that are produced in higher amounts as a function of increasing toxicity by developing relative difference plots. The highlighted compounds most likely contributing to the difference in acute toxicity expressed by the cultures are considered suspect molecules. Prymnesins were among the highlighted compounds.

## Ecotoxicological Impact of Multiple Stressors in Aquatic Ecosystems

**25 Effects of salmon lice medicine (diflubenzuron) on non-target shrimp populations under climate change: From experiments to population-level endpoints**

*J. Moe, Norwegian Institute for Water Research (NIVA) / Section for Catchment Processes; E. Ravagnan, International Research Institute of Stavanger / IRIS; D. Hjermann, NIVA Norwegian Institute for Water Research; R. Bechmann, International Research Institute of Stavanger*

The continued growth of marine aquaculture production has presented the industry with environmental and production concerns, of which the ectoparastic salmon lice (*Lepeophtheirus salmonis*) has gradually become a major problem. A commonly used pesticide against this crustacean is diflubenzuron (DFB), which acts as a chitin synthesis inhibitor and thereby interfere with the moulting stages during sea lice development. However, DFB from medicine feed may also affect non-target crustaceans such as the Northern shrimp (*Pandalus borealis*), which is an economically and ecologically important species in Norwegian fjords. Laboratory experiments have demonstrated that shrimp exposed to DFB through fish feed have reduced survival (ca. 60%) compared to control, in both the larval and the adult stages. Moreover, the effects of DFB exposure are more severe under future climate conditions (higher temperature and ocean acidification). The aim of this study is to make the information on these mechanistic effects more relevant for risk assessment at the population level. We have developed an age-structured population model representing a Northern shrimp population located in a hypothetical Norwegian fjord containing a fish farm, under both ambient and future climates. Our model is based on thorough knowledge of shrimp biology and clear results on toxicological effects from the laboratory experiments. Nevertheless, extrapolating the individual-level effects to the population level poses several challenges. Relevant information on shrimp populations in fjords is sparse (such as abundances, survival and reproductive rates, and density-dependent processes). The degree of exposure to medicine feed at different distances from aquaculture farms is also uncertain. We have therefore developed a set of model scenarios representing different medicine application schemes and different degrees of exposure for the shrimp populations. The purpose of the model is to predict effects of DFB exposure in combination with changed climatic conditions on population-level endpoints such as long-term abundance and age structure, and to assess the risk of population decline below threshold abundances.

**26 Ecotoxicoproteomics provides mechanistic insights into the alleviating effect of ocean acidification on mercury toxicity in marine copepod**

*Y. Li, M. Wang, Xiamen University*

Due to human activities, marine animals are suffering from multiple stressors, such as ocean acidification (OA) and mercury (Hg) pollution, for many generations; however, the mechanisms-of-action for long-term multigenerational exposure is poorly known, especially concering the interaction. Ecotoxicoproteomics is a relatively new displine that applies global proteomic technologies to toxicological studies, and it is aimed to determine critical proteins/processes affected by environmental stressors, hence figuring out the related mechanisms of action in organisms. In this study, using the copepod *Tigriopus japonicus* as a model species, shotgun-based quantitative proteomics, combined with phenotypic trait observation, is performed to investigate the biochemical mechanism about the effect of OA on Hg toxicity in marine animals under four generation exposure. Physiological observation analysis showed that OA significantly decreased Hg toxicity to reprodution in the copepod, however, which was resilient to reduced pH. Our proteomic analysis demonstrated that OA stress increased energy yielding in the copepod mainly via increased protein assimilation and proteolysis as a compensatory reaction, consequently rendering its physiological robustness to decreased pH. In contrast, Hg exposure decreased many critical processes, including ferric iron binding, antioxidant activity, cellular homeostasis, and glutathione metabolism, and these toxic events could translate into population-level responses, namely restrained reproduction in copepods. More importantly, the alleviation of Hg toxicity in *T. japonicus* by OA could be explained by the enhanced lysosome-autophagy pathway proteomes that are in charge of repairing/removing damaged proteins/enzymes under stress. Taken together, ecotoxicoproteomics is a powerful tool to provide molecular understanding about the response mechanisms of marine animals against multi-stressors.

**27 Copper Effects on Swimming Performance and Predator-Prey Interactions of Sailfin Mollies**

*T. Yanez Zapata, Florida International University (FIU) / Biological Sciences; R. Santana, Florida International University / Biology Section; J. Corrales, Florida International University (FIU) / Southeast Environmental Research Center; T. Crowl, Florida International University*

Copper (Cu) has been used over the last 50 years for its fertilizer properties in Florida. In 2005, over 250 thousand hectares in Florida were treated with more than 500,000 kg of Cu. In 2007, Cu contamination was ranked as one of the top-heavy metals accountable for the decrease in water quality in US water bodies by the USEPA. Due to the extensive use of Cu in Florida and its inability to degrade, Cu has accumulated and remains persistent in Florida's aquatic ecosystems. Exposure to Cu has been found to impair neurotransmitter and chemosensory functions in fish. An excellent method to study Cu sub-lethal effects is fish swimming performance. Saltwater intrusion due to global warming is also of concern in South Florida. The goal of this study was to determine the effects of Cu on [1] swimming performance in Sailfin mollies and [2] predator-prey interactions between largemouth bass and Sailfin mollies across a salinity gradient (freshwater and 8ppt saltwater). Fish (n=32) acclimated to FW or 8ppt saltwater were exposed to 7.20 – 8.20 ug/L Cu for 96 h. At the end of the exposure, fish swimming performance was determined by the critical swimming speed ($U_{crit}$, speed at which a fish cannot longer maintain position in the water column). $U_{crit}$was measured after a10 minute period at a water velocity of 10cm/s, followed by speed increases of 2 cm/s every 5 minutes until reaching 22 cm/s, when speed increases occurred every 15 minutes until the fish stopped swimming. The protocol was replicated to obtain Repetitive $U_{crit}$. Swimming performance ($U_{crit}$& Repetitive $U_{crit}$) was measured again after a 4-week-depuration period to determine if the fish were able to recover. In a separate study, Sailfin mollies (n = 60) were also exposed to 7.20 – 8.20 ug/L Cu; at 96 h, predator-prey interactions were assessed. In Phase 1, Sailfin mollies were presented to visual, chemical, or both visual and chemical cues and tested on predator avoidance. In Phase 2, predator-prey interactions were studied by introducing a live predator to determine prey mortality rate. Our results showed that swimming performance significantly decreased after a 96-h exposure and after a 4-week-depuration period, fish were able to return to their baseline $U_{crit}$. Cu had an effect on visual, chemical, and visual + chemical cues on prey in both Phases 1 and 2. Adverse effects of Cu on fish swimming performance and predator-prey interactions can result in a decline in population survival.

**28 Embryotoxicity and oxidative stress of the ternary mixture of aluminum, iron and mercury on Cyprinus carpio and Danio rerio**

*M. Galar-Martinez, S. Cano-Viveros, E. Gasca-Pérez, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional; S. Garcia-Medina, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional / Laboratory of Aquatic Toxicology / Department of Pharmacy; L.M. Gómez-Oliván, Universidad Autonoma del Estado de Mexico / Farmacia; K. Ruiz-Lara, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional / Laboratory of Aquatic Toxicology / Department of Pharmacy; F. Mena-Calderón, M. Paez-Osuna, E. Martínez-Galero, Escuela Nacional de Ciencias Biológicas Instituto Politécnico Nacional*

Aluminum, mercury and iron have been found in high concentrations around the world in different water bodies and have been shown to be very harmful for hydrobionts, causing metabolic dysfunctions and toxic effects at various levels, being the embryonic stage one of the most susceptible to damage. Although contaminants in water bodies usually occur in mixtures, few studies are made taking into account the interaction that could exist between them, this being a factor that can modify the toxic response in exposed organisms. *Cyprinus carpio* and *Danio rerio* are species in which the toxicity produced by metals can be observed effectively. In this study, the embryos of both species were exposed to the tertiary mixture of Al, Hg and Fe at concentrations equivalent to the maximum permissible limit for the protection of aquatic life, from fertilization to hatching. During this period, possible congenital malformations were assessed, as well as oxidative stress (degree of lipoperoxidation, content of oxidized proteins and hydroperoxides and activity of SOD, CAT and GPx) at 12, 24, 48, 72 and 96 h. The results obtained show that the mixture of these metals produces modifications to the embryonic development and alterations in the activity of the antioxidant enzymes and increase in the degree of lipoperoxidation, oxidized proteins and hydroperoxides in both species. In *Cyprinus carpio* the increased oxidative effect was observed mainly at 72 and 96 hours. In studies conducted with metals in isolation, it was found that neither iron nor mercury exert toxicity on embryos by oxidative stress, so there is a possibility that some of these metals are exerting an effect of potentiation on aluminum to increase the toxicity in the mixture, since this last metal turned out to be the main element that produced damages in embryos. As for *Danio rerio*, alterations in the activity of antioxidant enzymes and damage to biomolecules were observed in the different exposure times. It is concluded that the effect of the three metals is altered by the interaction between them and that interaction studies are necessary because in the environment the contaminants are in complex mixtures that can change the toxic effect of isolated xenobiotics.

**29 Effects of coal mining-associated stressors on stream fishes**

*S. Ciparis, US Fish and Wildlife Service / Virginia Field Office; Z.P. Martin, Virginia Tech / Department of Fish and Wildlife Conservation; P.L. Angermeier, US Geological Survey / Virginia Cooperative Fish and Wildlife Research Unit; D.J. Orth, Virginia Tech / Department of Fish and Wildlife Conservation*

Coal mining promotes stream salinization and species imperilment in the central Appalachians, USA. Conductivity-based extirpation thresholds for stream fishes have been derived using field data from this region. However, mining-induced sedimentation and elevated trace element concentrations can confound salinization effects. We developed a mining intensity gradient for watersheds in the Virginia coalfield and assessed multiple levels of ecological organization to increase our understanding of how multiple stressors affect Appalachian stream fishes. Existing data on fish communities, conductivity, and physical habitat were evaluated for 83 streams. We selected 15 streams using a stratified random design and assessed population- and individual-level responses of two native species, *Rhinichthys obtusus* and *Etheostoma flabellare,* to the mining gradient and associated stressors, including sedimentation and aqueous concentrations of major ions and trace elements. Occurrence of *R. obtusus* was not affected by mining intensity. However, the proportion of age-0 individuals was negatively related to mining intensity and also to [Se] in ovary tissue, which was positively related to mining intensity, despite limited detection of aqueous Se (2 of 15 sites). Glutathione peroxidase activity in *R. obtusus* liver tissue was positively related to the mining gradient and ovary [Se], indicating a physiological effect of Se. Presence of *E. flabellare* was negatively related to conductivity, this species was not collected at sites with the greatest mining intensity. The *E. flabellare* sex ratio, as proportion of females, was negatively related to the mining gradient. The greater impact of mining-related stressors on females may reflect greater energy allocation to reproduction. During the *E. flabellare* spawning season, activities of two energy-dependent enzymes, total ATPase in gill tissue and glutathione reductase in liver tissue, were negatively related to the mining gradient. Overall, our results suggest that mining activities negatively affect stream fishes via a trophic-energetic pathway and demonstrate individual- population-level effects prior to local extirpation. Although major ions are a driver of observed relationships between mining and responses by fishes, our results highlight the importance of considering Se bioaccumulation in fishes residing in coalfield streams, as Se appears to be a more significant co-stressor than indicated by measurable aqueous concentrations.

**30 Development of Dissolved Oxygen Criteria in Suisun Marsh, Part of the San Francisco Bay-Estuary Region**

*S. Roy, Tetra Tech Inc. / Research and Development; J. Flippin, Tetra Tech, Inc / Center for Ecological Sciences; J.M. Diamond, Tetra Tech, Inc.; B. Baginska, K. Lunde, N. Feger, San Francisco Bay Regional Water Board*

Suisun Marsh is the largest tidal wetland in California, with a high diversity of aquatic life in its mix of open water sloughs and managed wetlands. The marsh is especially important as a habitat given its location within an urbanized estuary, and downstream of the Sacramento-San Joaquin River Delta which is the focus of large-scale restoration efforts. However, discharges into sloughs and limited flushing have affected dissolved oxygen (DO) levels in some open waters of the marsh, with adverse effects on aquatic life. Other constituents of concern include mercury, nutrients and organic carbon loading. To address these impairments, the San Francisco Bay Water Board has adopted a Total Maximum Daily Load (TMDL) for Suisun Marsh. A key component is a new set of DO water quality objectives for the open waters of the marsh. Here we describe the process used to develop DO criteria in the marsh, based on several refinements of EPA's Virginian Province approach. From the list of species present in the marsh, we identified surrogate species with toxicological data on DO effects. Surrogate species selection was a key step since published toxicological studies on DO are available for a small number of relevant species. Literature data on DO effects were used to define DO criteria for chronic and acute exposure time frames (day, week, and month). This work also made use of continuous DO data from reference stations, collected over a decade, and data on fish abundance in the marsh from monthly trawls conducted over 17 years to evaluate naturally attainable expectations for DO. The new DO objectives are intended to protect against the adverse effects of low DO on survival, growth, reproduction, and behavior of fish in the marsh and to accommodate both spatial and temporal aspects of low oxygen events. This is the first effort since 1975 to refine DO water quality objectives in the San Francisco Bay region, and may have broader application for other tidal marshes on the California coast.

**31 Bioeffects Assessment in Bristol Bay, Alaska**

*S.I. Hartwell, D.A. Apeti, A. Pait, NOAA NOS / National Centers for Coastal Ocean Science Center for Coastal Monitoring and Assessment; T. Radenbaugh, University of Alaska Fairbanks / Bristol Bay Campus; R. Britton, USDA Forest Service / Chugach National Forest*

A baseline environmental characterization of the northern reaches of Bristol Bay, Alaska was conducted using the sediment quality triad approach (chemistry, toxicity, and benthic invertebrate community structure), along with measures of contaminant body burdens and the characterization of parasites and disease in starry flounder (Platichthys stellatus) and rainbow smelt (Osmerus mordax). The study area was subdivided into 6 strata based on geophysical and hydrodynamic characteristics. Within each stratum, a stratified random sampling approach was used to select sampling sites for surficial sediment. Concentrations of over 150 organic contaminants and metals were analyzed. Ambient toxicity was assessed using two bioassays (Microtox® and sea urchin fertilization and development). Habitat conditions (depth, salinity, temperature, dissolved oxygen, sediment grain size, and organic carbon content) were also measured. The study results indicated that organic contaminants, including polycyclic aromatic hydrocarbons (PAHs), were low relative to NOAA's sediment quality guidelines (SQG). Tributyltin was detected at trace levels only in Dillingham Harbor. Polychlorinated biphenyls (PCBs) and other chlorinated organic contaminants were detected only in trace amounts in the sediment. Sediment metal concentrations were very low; all values were below NOAA sediment quality guidelines (SQGs), except for arsenic. Benthic communities were relatively sparse at most locations due to harsh physical conditions. Species richness and diversity had no correlation to grain size, TOC, depth, or location when outliers were removed. Significant chemical toxicity was virtually absent except for high porewater ammonia levels at selected locations, associated with fish processing waste streams. Contaminant body burdens and histopathological lesions were very low in the fish tested. Except for an occurrence of an external papilloma condition and the observation of mild to moderate accumulation of macrophage aggregates in the spleen and/or kidney in some flounders, the fish were generally healthy and non-contaminated. In general, the bay appeared to be a robust environment with a biologically diverse benthic assemblage. A follow up study may be needed to assess if the ammonia issue has a significant impact on the overall biological system. We also need to investigate the fate of the fish waste to see whether it is taken up by the benthic or the pelagic food web.

### 32 Comparison of Ecologically and Economically Valued Aquatic Organisms in the Analysis of Fungicide Exposure

*E.N. Vebrosky, Louisiana State University / Department of Environmental Sciences; W. Xu, Louisiana State University AgCenter / Renewable Natural Resources; K. Armbrust, Louisiana State University / Environmental Sciences School of the Coast and Environment*

The fungicide dicloran is a model compound for analyzing the impacts of pesticide exposure to non-target aquatic organisms, taking external factors such as sunlight, salinity, and sediment into account for the experimental design. Fathead minnows (*P. promelas*) are a commonly used freshwater vertebrate species in toxicological assays, while red swamp crayfish (*P. clarkii*) are a non-traditional freshwater aquatic invertebrate for toxicological assays. Minnows are a beneficial representation of an ecologically valuable organism in freshwater systems and crayfish are not only ecologically valuable in many systems but in regions such as south Louisiana, they are also considered to be an economically valuable organism. Previous studies have shown that dicloran undergoes photolysis in laboratory analyses, degrading via a quinone-hydroquinone pathway. While the photodegradation half-life of dicloran is not impacted by salinity, it does affect the generation of intermediate products. The presence of sediment slows the overall dissipation of dicloran as sediment partitioning acts as a competitive sink against photolysis in the overlying water. Crayfish are benthic macroinvertebrates and therefore are at risk for exposure to pesticide exposure by runoff in the water column and pesticide partitioning into the sediment. Exposure to dicloran and simulated sunlight for fathead minnows estimated a $LC_{50}$ of 0.23 mg/L, with no mortality observed in dark exposures; crayfish exposed to dicloran and simulated sunlight showed more resilience with an estimated $LC_{50}$ between 0.50 and 1.0 mg/L without the presence of sediment. Dicloran has also been shown to be toxic and phototoxic to non-target aquatic organisms including eastern oysters and inland silversides.

## Advancing -omics into Regulatory Frameworks: Case Studies and Perspectives

### 33 Case Study: Estimation of Points of Departure for Estrogen Disrupting Substances in Fish Using Toxicogenomics

*F. Page-Lariviere, D. Crump, J. O'Brien, Environment and Climate Change Canada / National Wildlife Research Centre*

Traditional toxicity methods for ecological hazard evaluation of substances are expensive, time-consuming and focus on lethality and acute effects. Toxicogenomics may represent a viable alternative for estimating conservative points of departure (PoD) for chemicals with potential chronic toxicity. In this case study, we demonstrate that dose-response modeling of the transcriptomic response following short-term exposures can be used to estimate conservative PoDs for estrogen-disrupting substances (EDS). Publicly available transcriptomic datasets (n=6) from fish models (various tissues) exposed to multiple doses (>3) of three EDS (bisphenol A, ethinylestradiol, and diethylstilbesterol) were analyzed using BMDExpress (v.2.2). Our goal was to establish transcriptomic benchmark doses (BMDs) that could be used as PoDs for ecological hazard evaluation. In addition, differentially expressed genes were grouped into biological processes based on gene ontology terms, and process-specific BMDs were determined. To test for potential bias related to data processing, our analysis compared the effect of different normalization (fastlo, cyclic loess, lumi quantile, and vsn) and filter methods (ANOVA and Williams, with/without FDR and/or fold-change filter) on the transcriptomic BMDs. The resulting BMDs were then compared to the empirically-derived apical NOAEL (no observable adverse effect level) of each substance. We found that both normalization and filtering methods affect the final BMDs (approximately 1500-fold difference), accentuating the importance of consistent data processing for inter-study comparisons. BMDs were also impacted by the dose range tested, highlighting a preference for experimental designs containing multiple doses over a wide range of concentrations. Nevertheless, the comparison of most of the transcriptomic BMDs with apical NOAELs revealed close similarities between methods, suggesting that toxicogenomic dose-response modeling has the potential to be a protective decision-support tool for compounds with chronic toxicity, such as EDS.

### 34 The Environmental-Predictive-Information-Connectivity map (EPIC-map)

*C. Iosif, University of Liverpool; P. Antczak, University of Liverpool / Institute of Integrative Biology*

The adverse outcome pathway framework (AOP) has provided the ecotoxicology community with a great framework to conceptualise the knowledge generated in recent years. Particularly, with the advent of 'OMICs' approaches, knowledge has been generated on a large number of environmental stressors. Central to this framework is the AOPWiki which currently holds just over 200 different AOPs with varying amount of detail. Although AOPs are inherently stressor-free, i.e. an AOP is defined by the progression from a molecular initiating event (MIEs) to a phenotypic outcome through key events (KEs), the identification and development of AOPs is highly guided by the selection of stressors. In addition, to identify what MIEs a given stressors might activate, and whether it is sufficient to cause the observed phenotypic effect, can be challenging. To reduce the amount of time to identify suitable MIEs and KEs, given a novel stressor, a data driven approach is required that combines the power of OMICs, QSAR and Read-across approaches in a single easy to use software solution. The EPIC-map addresses this need by developing a single dataset of dose response relationships across more than 150 compounds of environmental concern in *Danio rerio* embryos including any observable adverse outcomes (AOs) and transcriptional response at concentrations below LC5 both linked to the structural features of the stressors. To access this data, we develop a web-based user interface by which the predictive and network models can be easily interrogated either with your own data or by selecting a compound from the pubchem database. To date the EPIC-map contains dose response curves for over 250 individual compounds of which 160 are currently subjected to transcriptomics screening. The aim of the EPIC-map is to provide the user with an easy to user interface to test and identify, *in-silico*, the likely AOPs (including a list of expected AOs), dose response curves and other important characteristics of chemicals that might be useful in prioritization, further testing or other components of environmental science. In this talk we will present the first unveiling of the EPIC-map, its ideas and predictive models that it uses in its current form and how it will integrate the different datasets and approaches to aid in AOP identification.

**35 Pathway-Based Approach for Chemical Classification Using Transcriptome**

*X. Pu, X. Zhang, Nanjing University / Environmental Science*

Deciphering the biological similarity between chemicals is a formidable challenge in read-across. Omics data has shown advantages in inferring high-resolution biological similarity by global molecular patterns. However, the application of omics data for chemical classification is limited due to the lack of in-depth analysis methods of elucidating biological similarity on pathway-based and dose-dependent levels. Here, we proposed a pathway-based framework for chemical classification, which integrates biological potency and enrichment scores of pathways derived from dose-dependent transcriptomics data. A case study was conducted on 17 (non-)genotoxic chemicals. A recently developed reduced human transcriptomics (RHT) approach was used to generate wide dose-dependent transcriptional expressions of 1200 human genes for each chemical, followed by evaluating the performance for chemical classification by each of three typical pathway analysis methods, including point of departure analysis (PODA), over representation analysis (ORA) and gene set enrichment analysis (GSEA). PODA can characterize transcriptomics-based biological potency which can clearly distinguish high potent genotoxicants and low potent negative controls, but cannot discriminate medium potent genotoxic and non-genotoxic chemicals. For characterization of enriched pathways, ORA can only provide statistical significance of pathways which showed poor performance for chemical classification, while GSEA can provide enrichment scores of pathways partially explainable by MOAs of chemicals, but GSEA method lacks potency information to improve classification performance. Integration of PODA and GSEA improves the accuracy of chemical classification, which stably separated all genotoxic and non-genotoxic chemicals under various weight of indexes by using ToxPi. Overall, biological potency derived from PODA and enrichment scores derived from GSEA were proposed to be combined as integrative indexes, which can promote pathway-based approach for chemical classification.

**36 A landscape-based approach to assess impacts from exposure to complex environmental mixtures in the Shenandoah River**

*D. Bertolatus, University of Colorado Denver / Integrative Biology; L.B. Barber, US Geological Survey / National Research Program; C.J. Martyniuk, University of Florida / Physiological Sciences; A.M. Vajda, University of Colorado Denver / Integrative Biology*

Aquatic habitats are often contaminated with complex mixtures of chemicals originating from diverse sources. Different sources of contaminants may be associated with different land uses in surrounding watersheds. Thus, land use and other landscape-scale metrics may be informative for understanding patterns of pollution and exposure effects. Here, we employed integrated chemical and biological analyses to determine how mixture composition and exposure effects varied between sites with different land use. Adult fathead minnows (*Pimephales promelas*) were exposed to water from different locations within the Shenandoah River watershed in mobile, in situ laboratories. Exposure locations included agricultural, urban, waste-water impacted, mixed-use, and forested sites. It is reasoned that the association between landscape variables and chemical occurrence depends on the scale at which landscape variables are measured. Therefore, exposures were conducted at the watershed scale, as well as the site scale, with multiple locations within a single river reach. Multiple biological endpoints were measured, including gonadosomatic index (GSI), number of nuptial tubercles, plasma vitellogenin, and hepatic gene expression. Water samples were taken during the fish exposure and analyzed for more than 460 chemical constituents. Each location had a unique chemical profile that was generally consistent with landuse. Whole-organism and molecular responses also differed between the sites. At a waste-water impacted site, organismal and tissue biomarkers of endocrine disruption were significantly affected, including decreased GSI, altered secondary sex characteristics, and decreased sperm abundance. However, molecular biomarkers of estrogen exposureshowed no difference between sites, suggesting that estrogen receptor activation was likely not a mechanism for these adverse outcomes. Fish exposed at an agriculture-impacted site had increased mortality and decreased GSI relative to initial controls, which was accompanied by differential regulation of immune and metabolism related pathways at the transcript level. Lastly, hierarchical clustering of hepatic transcriptome profiles showed a site-specific pattern, demonstrating that sites with differing landuse exert unique exposure effects at the transcript level. The continued study of the relationships between land use, chemical occurrence, and exposure effects is expected to yield predictive tools for risk assessment and management.

**37 Incorporating transgenerational epigenetic inheritance into ecological risk assessment frameworks: A heavy metal case study**

*J. Shaw, CSIRO / Land and Water*

Detrimental heritable modifications to organisms could be induced by chronic exposure to environmental contaminants. However, to what extent transgenerational inheritance occurs is still disputed. We carried out numerous multi-generation epigenetic-focused plant experiments to evaluate transgenerational inheritance. Our experiments extended to the F3 generation, beyond what could be deemed “direct exposure” to F1 and F2 gametes, and also included subsequent non-exposed generations to evaluate transgenerational recovery times. To examine the apparent irreproducibility of current transgenerational studies we assessed these effects in two distinct model plant species under controlled conditions, using two well-studied contaminants: the heavy metals, silver and copper. We collected both morphological data and reduced representation bisulphate sequencing data to assess the prevalence of transgenerational effects. We attempt to correlate epigenetic end points with observable organism changes before determining a need for transgenerational risk management. Furthermore, we propose a regulatory framework and optimal experimental design that enables transgenerational epigenetic effects to be assessed and incorporated into conventional ecotoxicological testing in a more useful manner.

**38 Selenomethionine induced molecular toxicity in the fathead minnow (*Pimephales promelas*)**

*D. Green, University of Saskatchewan / Toxicology Centre; D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences; K. Liber, University of Saskatchewan / Toxicology Centre; N. Hogan, University of Saskatchewan / Toxicology Centre and Department of Animal and Poultry Science, College of Agriculture and Bioresources; A.J. Alcaraz, University of Saskatchewan / Toxicology Centre; T. Lane, University of Saskatchewan; K. Raes, University of Saskatchewan / Toxicology Centre; K. Bluhm, University of Saskatchewan / School of Environment and Sustainability; M. Brinkmann, M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre*

Selenium is a naturally occurring trace element anthropogenically released to the aquatic environment from activities such as mining and fertilizer application. Within the aquatic environment, primary producers convert aqueous phase selenium oxyanions to organic species, including selenomethionine (SeMet), which can bioaccumulate and cause ecological harm, typically at the top of aquatic food webs. Excess SeMet exposure is known to cause several physiological alterations including oxidative stress and altered stress response. Ingestion of elevated concentrations of SeMet can cause direct toxicity to exposed animals, as well as aggregate in the yolks of oviparous animals and potentially lead to complete recruitment failure through embryotoxicity. However, there is still uncertainty regarding the specific mechanisms by which SeMet causes these pathologies. Therefore, the goal of this study was to conduct an in-depth characterization of the molecular mechanisms underlying SeMet toxicities with the aim to identify molecular toxicity pathways that enable prediction of pathologies before they occur. This study exposed adult fathead minnows (*Pimephales promelas*) to graded concentrations of dietary SeMet (1.18 µg/g dry weight control, and 3.88, 8.75, and 29.58 µg/g dry weight treatments) for 28 days in order to determine its effects on biochemical and molecular processes in this species. Thiobarbituric acid reactive substances, reduced to oxidized glutathione ratios, superoxide dismutase, and catalase assays are being employed on liver tissues to determine the extent of oxidative damage, while liver whole transcriptome and proteome analyses are being conducted to determine molecular toxicity pathways characteristic of SeMet exposure in these fish. These results are then intended to validate and inform the development of critical molecular endpoints of SeMet toxicity in fish that will be used to inform the generation of the EcotoxChip (@ecotoxchip), a qPCR microarray screening tool ultimately intended to expedite the risk assessment of chemicals and mixtures of potential environmental concern.

**39 Assessment of the transcriptome in tree swallow (*Tachycineta bicolor*) nestlings from Great Lakes Areas of Concern**

*C. Tseng, Baylor University / Environmental Science; T.W. Custer, C.M. Custer, P. Dummer, US Geological Survey / Upper Midwest Environmental Sciences Center; N.K. Karouna-Renier, USGS Patuxent Wildlife Research Center; C.W. Matson, Baylor University / Environmental Science*

Polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), polychlorinated dibenzo-p-dioxins and dibenzo-furans (PCDD/PCDFs), and a variety of pesticides and other contaminants of emerging concern (CECs) are significant issues in Areas of Concern (AOC) on the Great Lakes. Pharmaceuticals and personal care products have become major CECs with limited knowledge of the effects of dietary exposure to terrestrial animals. Tree swallow (*Tachycineta bicolor*) nestlings were collected from 27 AOCs and nine nearby non-AOC sites from 2010 to 2015. Contaminant analyses and biomarkers were examined in all nestlings collected. In 2016, nestlings were collected from six locations on the Maumee River to evaluate CECs, including pharmaceuticals and personal care products. Transcriptomic responses were evaluated in nestlings collected from selected sites on the Great Lakes and the Maumee River. RNA-Seq library construction and sequencing were done with Illumina chemistries. *De novo* assembly and downstream differential gene expression (DGE) analyses utilized the Trinity platform and its suggested workflow. In addition, a combined *de novo* Transcriptome assembly (CDTA) was used to improve the completeness of the assembled transcriptome. Assembly completeness is 89.2%, as measured via BUSCO using vertebrate single-copy orthologs. We found that the CDTA approach reduced redundancy by 80% in the assembled transcriptome. Differential gene expression was correlated with geological location for the samples collected over the entire Great Lakes area, including within the higher resolution sampling along the Maumee River. Dietary PAHs could explain the separation in biomarkers of oxidative stress and the gene expression of several Nrf2-regulated antioxidant genes. Correspondence analysis was used to describe the correlation between each gene expression cluster with similar molecular functions and the contaminant profiles from the same nestling.

**40 De novo transcriptome assemblies and transcriptional profiling of 16 Fundulus killifish species in response to environmental challenge**

*L. Johnson, R.S. Brennan, University of California Davis / Environmental Toxicology; T. Brown, University of California Davis / Population Health & Reproduction; A. Whitehead, University of California Davis / Environmental Toxicology*

Transcriptomic resources and methods are increasingly being used for chemical safety testing in a few standard species. With advances in technology, these tools can now be readily developed for diverse species, and thereby enable chemical safety testing that is tailored, for example, to native species of concern or to enable cross-species extrapolation. However, a lack of robust tools for reproducible assembly and annotation of reference transcriptomes, and methods to analyze expression across species in a phylogenetic context that enables direct species to species comparisons, currently limits the science. Here we present a robust and reproducible informatics pipeline for the *de novo* assembly and annotation of transcriptomes from sixteen killifish species from the genus *Fundulus*. We use this matrix of annotations to directly compare multi-species responses to environmental challenge. We discover patterns of shared or diverged gene expression in the context of phylogenetic relatedness in addition to species-specific differences in sensitivity to the environmental challenge. Though our proof of principle includes challenge to salinity, our workflow provides a framework for tool development and cross-species contrasts to any environmental challenge including toxicants. This provides a template for development and deployment of transcriptomics tools and methods to be used for transcriptional profiling in a broad range of species to enable mechanistic insight into responses to environmental change, including pollution. Risk assessors and environmental managers can thereby access insights derived from mechanistic responses of specific and diverse groups of species.

## Bioavailability-Based Aquatic Toxicity Models for Metals

**41 State of the Science of Metals Bioavailability in Natural Waters**

*W.J. Adams, Red Cap Consulting; R. Blust, University of Antwerp / Department of Biology / SPHERE Research Group; R. Dwyer, International Copper Association / Health, Environment and Sustainable Development; D. Mount, USEPA / ORD / NHEERL / Mid-Continent Ecology Division-Duluth, MN; E. Nordheim, European Aluminum; P. Rodriguez, PHR Consulting; D.J. Spry, Environment and Climate Change Canada / Water Policy & Coordination Direct*

As part of the SETAC Workshop on Metals Bioavailability, December, 2017 the history of the development of metal bioavailability concepts was reviewed. This presentation gives an overview of metal bioavailability developments for aquatic organisms, development of models and application to bioavailability-based water quality criteria and standards. Metals are widely studied environmental contaminants due to their ubiquity, potential toxicity to aquatic life, and tendency for their aquatic toxicity to vary widely with the chemistry of the surface water in which they occur. The implications of metal bioavailability for ecological risk assessment are large, as it can produce differences in toxicity of more than 100-fold across a range of water chemistries in surface waters. Beginning as early as the 1930s, considerable research effort has been expended in an attempt to document and understand metal bioavailability, as a function of total and dissolved metal, water hardness, natural organic matter (NOM), pH, and other characteristics of natural waters. The growing understanding of these factors, and improvements in both analytical and computational chemistry, led in turn to a series of modeling approaches intended to describe and predict the relationship between water chemistry and metal toxicity, including the Free Ion Activity Model (FIAM), the Gill Surface Interaction Model (GSIM), the Biotic Ligand Model (BLM), and additional derivatives and regression models that arose from similar knowledge. The arc of these scientific advances can also be traced through the evolution of USEPA Ambient Water Quality Criteria over the last 50 years, from guidance in the "Green Book" published in 1968, to metal-specific criteria produced in the last decade. Through time, these criteria have incorporated increasingly sophisticated means of addressing metal bioavailability, as has regulatory guidance developed by jurisdictions across the globe. These actions have shifted the debate toward identifying harmonized approaches for determining when knowledge is adequate to establish bioavailability-based approaches and how best to implement them into regulatory practice.

**42 Metal bioavailability models: Current status, lessons learned, considerations for regulatory use, and the path forward**

*C.A. Mebane, US Geological Survey / Idaho Water Science Center; M.J. Chowdhury, International Lead Association; K.A. De Schamphelaere, Ghent University / Applied Ecology and Environmental Biology; S. Lofts, NERC Centre for Ecology & Hydrology / Shore Section; P.R. Paquin, HDR / Water Quality Modeling; R.C. Santore, Windward Environmental, LLC; C.M. Wood, University of British Columbia / Zoology*

Since the early 2000s, biotic ligand models (BLMs) and related constructs have been a dominant paradigm for risk assessment of aqueous metals in the environment. We review the current status of metals bioavailability models and recommend considerations for their use and refinement. Striking a balance between comprehensive, mechanistically sound models or simplified approaches is a challenge; pH effects as a factor modifying metals toxicity are unique, with multiple possible mechanisms. As such, we doubt it is ever appropriate to lump algae and animal bioavailability models; however it is often reasonable to lump bioavailability models for animals, although aquatic insects may be an exception. Other recommendations include that data generated for model development should consider equilibrium conditions in exposure designs, including food items in combined waterborne-dietary matched chronic exposures. Some potentially important toxicity modifying factors are currently not represented in bioavailability models, and have received insufficient attention in toxicity testing. Temperature is probably of foremost importance; phosphate is likely important in plant and algae models. If empirical bioavailability tools such as multiple-linear regression models and look-up tables are employed in criteria, they should always be informed qualitatively and quantitatively by mechanistic models. If bioavailability models are to be used in environmental regulation, ongoing support and availability for use of the models in the public domain are essential.

**43 Guidance on the Development of Empirical Bioavailability Models for Metals**

*K. Brix, EcoTox / Marine Biology and Ecology; D.K. DeForest, L.M. Tear, Windward Environmental LLC; W. Peijnenburg, RIVM / Center for Safety of Substances and Products; A. Peters, wca; E. Traudt, Jacobs / Chemistry; R. Erickson, USEPA / ORD / NHEERL Mid-Continent Ecology Division-Duluth, MN*

Recently, there has been renewed interest in the development and use of empirical models to predict metal bioavailability and derive water quality criteria. However, there is considerable variability in the conceptual and statistical approaches with which these models have been developed. We review several case studies of empirical bioavailability model development, evaluating and making recommendations on key issues, including: species selection, identification of toxicity modifying factors (TMFs) and the appropriate environmental range of these factors, use of existing toxicity data sets and experimental design for developing new data sets, statistical considerations in deriving species-specific and pooled bioavailability models, and normalization of species sensitivity distributions using these models. We recommend that TMFs be identified from available chemical speciation and toxicity data, and statistical evaluations of their relationships to toxicity. Experimental designs for new toxicity data must be sufficiently robust to detect non-linear responses to TMFs and should encompass a large fraction (e.g., 90%) of the TMF range while avoiding TMF combinations that are unlikely to occur in natural waters. Model development should involve a rigorous use of both visual plotting and statistical techniques to evaluate data fit. When data allow, we recommend using a simple linear model structure and developing pooled models rather than retaining multiple taxa-specific models. We conclude that empirical bioavailability models often have similar predictive capabilities compared to mechanistic models and can provide a relatively simple, transparent tool for predicting the effects of TMFs on metal bioavailability to achieve desired environmental management goals.

**44 Validation of Bioavailability-based Toxicity Models for Metals**

*E. Garman, NiPERA, Inc.; J.S. Meyer, Applied Limnology Professionals LLC and Colorado School of Mines; C. Bergeron, USEPA / Office of Water; T. Blewett, University of Alberta / Biological Sciences; W.H. Clements, Colorado State University / Fish, Wildlife and Conservation Biology; M. Elias, USEPA / Office of Water; K.J. Farley, Manhattan College / Civil and Environmental Engineering; F. Gissi, CSIRO Oceans and Atmosphere; A.C. Ryan, Windward Environmental LLC*

Environmental agencies world-wide are increasingly incorporating bioavailability-based toxicity models into development of protective values for aquatic life such as water quality criteria, standards, and/or guidelines for metals. Use of such models to develop protective values should be contingent upon their ability to meet performance criteria as specified through a model validation process. Model validation generally involves an assessment of a model's appropriateness, relevance, and accuracy (i.e., Is it "fit for purpose"?). We review existing guidance for validation of bioavailability-based toxicity models, pose questions to be asked in model validation studies, discuss model study type and design considerations, present several new ways to evaluate model performance in validation studies, and suggest a framework for use of model validation in development of protective values for aquatic life. We conclude that model validation should be rigorous, but flexible enough to meet the performance criteria established for the model and fit the model's purpose. Although a model can never be fully validated to a level of zero uncertainty, it can be sufficiently validated to fit a specific purpose. Therefore, the level of support for a model should be presented/reported in such a way that the user can choose the level of acceptability consistent with the model's purpose. Models should be validated using experimental designs and endpoints consistent with the datasets that were used to parameterize and calibrate the model, and they should be validated across a broad range of geographically- and ecologically-relevant water types. Model validation is a continuous and iterative process that will necessarily be constrained by the amount of data available. It is important to recognize that models have a lifecycle and that scientific knowledge will continue to advance along with the collection of additional data. As models advance, they might need to undergo additional validation. In the future, as more models are developed and refined to predict population-, community-, and ecosystem-level effects of metals, validation methodology will have to evolve to meet those needs.

**45 Derivation and Application of Thresholds for Metals Using Bioavailability-Based Approaches**

*R. Gensemer, GEI Consultants / Ecological Division; E. Van Genderen, International Zinc Association; J. Stauber, CSIRO / CSIRO Land and Water; C.G. Delos, Great Lakes Environmental Center; D.M. Eignor, USEPA / Office of Water; J. McGeer, Wilfrid Laurier University / Department of Biology; G. Merrington, WCA Environment Limited; P. Whitehouse, Environment Agency*

An overview will be provided regarding best practices for evaluating bioavailability models for metals for use in the protection of aquatic life. This presentation will include descriptions of the state of the science regarding a) the evaluation and selection of ecotoxicity data, b) the selection of bioavailability models for use in normalization, and c) subsequent application of bioavailability models. While many examples of normalization steps exist worldwide, a scheme is proposed to evaluate and select a model that takes account its representativeness (water chemistry and taxonomic coverage of the ecotoxicity dataset) and validation performance. Important considerations for a suitable model are the quantity of inputs needed, accuracy, and ease of use; all of which are needed to set protective water quality values for metals and to use these values to evaluate potential risks to receiving waters. While the end results of different model application approaches may be broadly similar, the differences in these application frameworks ultimately come down to a series of tradeoffs between who needs to collect the data and use the bioavailability model, the different requirements of spatial scales involved (e.g., regional vs. site-specific values), and a balance between accuracy and expected protectiveness.

Ultimately, understanding the limits and consequences of these tradeoffs allows for balance between accuracy of aquatic life protection and intended levels of protection.

**46 Application of the Biotic Ligand Model (BLM): A Case Study in Assessing Metals Risk to Vernal Pool Species**

*S. Thakali, AECOM; W.J. Reese III, AECOM / Risk Assessment; R.G. Stahl, T.E. Stilley, E.I. DuPont de Nemours and Company / Corp Remediation*

An ecological risk assessment (ERA) is being performed at a former munitions manufacturing site in Connecticut. The majority of the site is forested upland habitat, with limited or no contaminant migration pathways associated with historical activities; aquatic and ephemeral and permanent wetland habitats are also present, including vernal pools. As such, exposure of vernal pool biota to site-related metals is being evaluated as part of the ERA. A screening evaluation of existing wetland and vernal pool surface-water data indicated potential for ecological risks associated with copper, lead, and nickel based on exceedance of applicable ecological screening values, including hardness-based Water Quality Criteria for Aquatic Life (WQCs). However, the initial screening did not account for two site-specific factors in assessing potential risk due to metals in vernal pools and aquatic habitats: site-specific metals bioavailability and site-specific receptors of concern (ROCs), including the obligate vernal pool invertebrate and amphibian species. To account for site-specific metals bioavailability, sample-specific WQCs were calculated based on the application of the Biotic Ligand Model (BLM) for copper. The BLM incorporates site-specific bioavailability-modifying factors such as dissolved organic carbon (DOC), pH and alkalinity. For the existing datasets with estimated DOC and alkalinity, exceedances of BLM-based WQCs for copper were minor, indicating generally limited aquatic bioavailability of copper at the site. To further account for the site-specific ROCs, amphibian-specific No Observed Effect Concentrations (NOECs) were derived based on literature data. Metals exceedances were also generally minor relative to the amphibian-specific NOECs, indicating that the potential risk to an important group of site-specific ROCs is likely limited. Surface-water samples were collected recently in May 2018 to represent current site conditions, to fill data gaps for refined evaluation of bioavailability, and to capture the most relevant season for aquatic exposure of vernal pool species. Ongoing evaluation of the current data includes an initial screening and subsequent refinements using BLM-based WQC for copper and amphibian-specific NOECs. The focus of this presentation will be the results of the BLM-based evaluation of site-specific metals bioavailability and toxicity and consideration of site-specific ROCs for the on-site vernal pools and wetland habitats.

**47 Influence of water chemistry on the chronic toxicity of nickel and zinc to the mayfly Neocloeon triangulifer in natural waters**

*D.J. Soucek, Illinois Natural History Survey; A. Dickinson, Illinois Natural History Survey / Ecology; C.E. Schlekat, NiPERA; E. Van Genderen, International Zinc Association*

Many states currently rely on dated hardness-based criteria for regulation of nickel and zinc in surface waters. Resistance to adoption of criteria based on the biotic ligand model (BLM) is based in part on uncertainty about whether these models can reliably predict toxic effects of nickel (Ni) and zinc (Zn) on diverse assemblages of aquatic biota across the wide range of water quality conditions occurring in the region. Examination of water quality data across different ecoregions within Region 5 (Great Lakes/Upper Midwest) identified two areas with extreme values of several water chemistry parameters: the 'Northern Lakes and Forests' (NF) ecoregion of Minnesota, Michigan, and Wisconsin has a high frequency of low pH/low hardness/high dissolved organic carbon (DOC) waters, and the Corn Belt (CB) ecoregion of Iowa and Illinois has many waters with high hardness, high pH, and high alkalinity together with low to moderate DOC concentrations. Another area of uncertainty in the application of Ni and Zn BLMs is whether models developed based on responses of a limited number of invertebrates and fish can adequately predict toxicity to the full range of aquatic invertebrate taxa. The objective of this research was to estimate the representative Ni and Zn sensitivities for the mayfly, *Neocloeon triangulifer*, based on chronic tests with four natural waters, two from NF and two from CB. We also sought to evaluate whether BLM models can explain variation among Ni and Zn effect concentrations across a range of water chemistries as effectively for mayflies as for *Ceriodaphnia dubia*. The mayfly was more sensitive to Zn than to Ni, with EC20s for Ni being 2 to 6 fold higher than those for Zn. Dissolved organic carbon appeared to have a strong influence on toxicity to the mayfly. For example the Ni EC20 in the high DOC low hardness NF waters were ~2 to 9 fold higher than EC20s in the low DOC high hardness CB waters. These observations are consistent with bioavailability models developed for other aquatic species. Results of this research will broaden the geochemical and taxonomic ranges of validation of Ni and Zn bioavailability models.

**48 Overview of EPA's Cooperative Research and Development Agreement with metals associations to develop a simplified metals modeling approach**

*C. Bergeron, K. Gallagher, USEPA / Office of Water; W.J. Adams, Red Cap Consulting; M.J. Chowdhury, International Lead Association; C. Claytor, Copper Development Association Inc. / HESD; R. Dwyer, International Copper Association / Health, Environment and Sustainable Development; E. Garman, NiPERA, Inc.; P. Marsh, Cobalt Institute; E. Nordheim, EHS Consultant; C.E. Schlekat, NiPERA; B.A. Stubblefield, Oregon State University / Environmental and Molecular Toxicology; E.J. Van Genderen, International Zinc Association / Environment & Sustainability; C. Wells, Aluminum Association*

EPA has entered into a Cooperative Research and Development Agreement (CRADA) with eight metals associations in order to leverage scientific expertise and resources of scientists inside and outside of the agency. The CRADA partners and other associated metals experts will collaborate to advance the use of novel scientific approaches for protecting aquatic life from toxic metal exposures. To date, EPA has developed recommended Aquatic Life Criteria for 10 metals (aluminum, arsenic, cadmium, chromium (III and IV), copper, iron, lead, nickel, silver, and zinc). Several of these criteria, however, were developed in the 1980's and do not reflect new toxicity studies or approaches for considering how water chemistry parameters (*e.g.*, pH, dissolved organic carbon, and hardness) can affect metal bioavailability and subsequent toxicity to aquatic species. For example, several recent Aquatic Life Ambient Water Quality Criteria (Freshwater Copper [2007], Draft Saltwater Copper [2016], and Draft Aluminum [2017]) have already been updated to reflect the influence of water chemistry on metal bioavailability using different approaches. This five-year CRADA will support the development of a simplified, overarching modeling approach for quantifying metal bioavailability and toxicity under the range of water chemistry conditions found in aquatic environments. Specifically, this research will include reviewing key modeling parameters and comparing the complexity, accuracy and usability of a variety of possible approaches (*e.g.*, biotic ligand model and multiple linear regression models) to develop a peer-reviewed overarching modeling approach that will reflect a streamlined data approach involving fewer water chemistry input parameters. Towards this objective, methods of model comparison were developed in a recent SETAC Technical workshop (December 2017) that identified best practices for metal bioavailability models.Using the overarching modeling approach as a framework, EPA will then collaborate with individual metals associations to develop metal-specific bioavailability models to support Aquatic Life Ambient Water Quality Criteria development. The modeling approach developed through the collaborative CRADA process will better support states, territories and tribes by providing updated metals criteria recommendations that reflect the most current science and are easier to implement than existing approaches.

## Advances in Passive Sampling Methods: Research to Application

### 49 Statistical comparison of performance reference compound (PRC)-based methods for calculating $C_{free}$

R.M. Burgess, USEPA / Atlantic Ecology Division; A. Joyce, National Research Council/ USEPA / Atlantic Ecology Division

Freely dissolved concentrations ($C_{free}$) have proven useful for estimating exposure concentrations of nonionic organic contaminants in the water column and sediment interstitial waters. It is critical that $C_{free}$ be determined under actual or modelled equilibrium conditions. Performance reference compounds (PRCs) are applied to model equilibrium conditions and estimate fractional equilibrium ($f_{eq}$) used to calculate $C_{free}$. Currently, there are four methods for using PRC data to calculate $f_{eq}$. This variety of methods can create confusion for inexperienced users as to which one to apply. The methods include assuming equilibrium (PRCs are not used), a first order model, a diffusion-based model, and an exchange rate-based model. In this analysis, the four methods were used to calculate $C_{free}$ for several PCB congeners and total PCBs in the water column of a contaminated sediment site. The resulting $C_{free}$ values were then compared statistically to identify trends between the methods. Low-density polyethylene (PE) in four thicknesses was used as a passive sampler and 27 PCB congeners served as the target chemicals. The deployment was performed in triplicate in the water column of three stations at the New Bedford Harbor Superfund site in New Bedford, Massachusetts (USA). Following the 30 day deployments, the four methods were used to estimate $C_{free}$ and these values were then compared statistically with ANOVA followed by Fisher's test. This analysis resulted in twelve comparisons of the multiple PCB congeners and total PCBs. In general, the diffusion-based and exchange rate-based methods resulted in statistically similar estimates of $C_{free}$ while assuming equilibrium often under-estimated $C_{free}$ and using the first order model generated $C_{free}$s statistically-different from the diffusion and exchange rate methods. For example, at the most contaminated site (NBH2), for the 12, 25, 51 and 76 µm PE thicknesses, the diffusion-based and exchange-rate methods $C_{free}$ values were statistically identical 68%, 36%, 68% and 32% of the time, respectively. Based on the comparability of the diffusion method $C_{free}$s to conventional measures of $C_{free}$ from literature studies, this statistical comparison indicates the diffusion-based and exchange rate-based models are the preferred methods to use for calculating accurate water column $C_{free}$s.

### 50 Standardization of Polymeric Sampling for Measuring Freely Dissolved Organic Contaminant Concentrations in Sediment

U. Ghosh, M. Bokare, University of Maryland, Baltimore County / Chemical, Biochemical and Environmental Engineering; M. Michalsen, US Army Engineer Research Development Center / Environmental Engineering & Technology Section; P. Gschwend, J.K. MacFarlane, Massachusetts Institute of Technology / Department of Civil and Environmental Engineering; D.D. Reible, A. Aribidara, Texas Tech University / Civil and Environmental Engineering; M. Lin, Pyron Environmental Inc.

Research over the past two decades has demonstrated that the freely dissolved concentrations ($C_{free}$) of hydrophobic chemicals are directly linked to sediment-dwelling organism's exposure to contaminants as well as risk for biouptake into the larger foodweb. Passive sampling methods using polymers can accurately measure $C_{free}$, but historically such measures have been considered research tools largely used by academic researchers. For widespread use in the field and for regulatory decision making, standardized methods are necessary that are accepted by regulatory agencies including the USEPA. The purpose of the present effort is to demonstrate standardized polymeric sampler procedures for measuring $C_{free}$ by multiple participating public- and private-sector analytical laboratories, thereby increasing commercial availability, promoting acceptance, and increased use. This standardization effort, supported by the DoD Environmental Security Technology Certification Program, is progressing through multiple steps of inter-laboratory comparison. In the first step, the laboratories agreed on a common set of performance reference compounds to be used for the measurement of polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs). In the second step, interlaboratory analysis of a common source calibration check standard showed most labs met the acceptance criteria of ±30% for all of the native target analytes and ±50% for PRCs for PAHs and PCBs. A few labs reported results for a few analytes that were slightly out-of-range (e.g. ±38% for one or two natives; ±58% for one or two PRCs). The third step involved the extraction and measurement of PCB and PAH PRCs loaded into polyethylene and polydimethylsiloxane passive samplers and showed most labs met the ±50% acceptance criteria for all the individual PCBs and PAHs. Next steps in the standardization effort involve evaluation of independent passive sampler preparation with loading of PRCs by each laboratory and the use of the samplers in a common homogenized sediment sample to measure $C_{free}$ for the target PAH and PCB compounds. Outcomes of this interlaboratory study are intended to fulfill the method validation requirement for a future SW846 method application.

### 51 Assessing diffusive and advective flux of PAHs across sediment-water and water-air phases at a legacy creosote site in the Pacific Northwest

C.C. Ghetu, Oregon State University; J. Minick, L. Tidwell, P. Hoffman, K.A. Anderson, Oregon State University / Environmental and Molecular Toxicology

This study focused on development of diffusive and advective flux of passive sampler devices (PSDs) at a legacy creosote site in the US PNW. PSDs and proto-type advective flux seepage meters with PSDs were co-deployed at sediment–water and water–air interfaces within and outside the site. PSDs were extracted and analyzed by gas chromatography mass spectrometry. Analyses included four instrumental methods encompassing parent and alkylated polycyclic aromatic hydrocarbons (PAHs), parent and alkylated PAHs specific to forensic source determination, oxygenated PAHs, and hopanes/cholestanes. Preliminary results show PAHs were detected in all compartments across all sites, with highest concentrations downstream. Compounds included phenanthrene and benzo[b]fluoranthene, currently found on the EPA Priority PAHs list. Concentrations of phenanthrene were 27.8 ng/L/80.3 ng/L in deep/shallow porewater, 5.63 ng/L in surface water and 44 ng/m3 in air downstream. We report each environmental compartment concentration, and the bulk movement of contaminants through the environment, referred to as flux. The diffusive flux of air, water and sediment has only recently been demonstrated for the first time with low density polyethylene passive samplers. Further data analysis will inform the direction and magnitude of diffusive PAH movement between the sediment, aqueous, and atmospheric phases at this heavily contaminated site. Additionally, we will report on the results of proto-type advective flux meters and co-deployed PSDs. Advective flux describes bulk movement of water and its contribution to the transport of contaminants, allowing us to take into effect factors such as tidal pumping, not accounted for in a static diffusive flux model. Combining these two components will allow us to better understand fate and transport of environmental contaminants. Forensic source identification determines contributions from pyrogenic and petrogenic sources, to provide insight into the potential impact of the facility on the surrounding area. Hopanes/cholestanes serve as biomarkers of petroleum products, and also help in sourcing multiple types of crude oil. OPAHs are photodegredate compounds of PAHs, have been understudied and can be more toxic than their PAH counterparts. Understanding contaminant movement across environmental phases at contaminated sites will help to inform managers and regulatory agencies responsible for the maintenance and decontamination of these locations.

### 52 Passive Porewater Sampling: From Academia to Consulting

*<u>L. Paulik</u>, Maul Foster & Alongi, Inc. / Environmental and Molecular Toxicology; M. Pickering, Maul Foster & Alongi, Inc.*

The research community has long accepted passive sampling as a useful tool for accurately measuring concentrations of organic contaminants in sediment porewater. However, obtaining regulatory approval to use these newer passive techniques can be challenging. In more recent years the regulatory community in the United States has been increasingly accepting and implementing passive sampling. This presentation will focus on an ongoing project that takes place in a freshwater pond in the Columbia Slough Watershed in Portland, Oregon. The pond provides habitat for sensitive native species, but it is contaminated with legacy PCB pollution. The site's property owner is working with the Oregon Department of Environmental Quality (DEQ) and Maul, Foster & Alongi (MFA) to prepare the remedial design for the pond. MFA developed a porewater passive sampling plan to establish baseline conditions and monitor the effectiveness of the remedy. This presentation will discuss challenges and lessons learned during development of the passive porewater sampling approach for this project. Care was taken to ensure that the approach would satisfy the guidelines outlined in "Laboratory, Field, and Analytical Procedures for Using Passive Sampling in the Evaluation of Contaminated Sediments: User's Manual", a guidance document on passive porewater sampling authored by the U.S. Department of Defense's Strategic Environmental Research and Development Program/ Environmental Security Technology Certification Program and USEPA's Office of Research and Development in 2017. MFA is planning to use SiREM's SP3 sampler to passively sample porewater before and after remedy implementation. One source of uncertainty with any passive sampling technique is the calculations used to convert concentrations in passive samplers to environmental concentrations. A major consideration in choosing a passive sampling approach was whether environmental data collected now would be directly comparable to data collected years in the future. SiREM provides users with both raw data from the passive samplers and environmental concentrations. This gave MFA's scientists confidence that the baseline data will be directly comparable to all future data collected with this SP3 sampler at this site, regardless of advances in passive sampling research.

### 53 Utilization of a novel passive sampler to detect PFASs in aquatic environments

*<u>C. Gardiner</u>, A. Robuck, J. Becanova, R. Lohmann, Graduate School of Oceanography / University of Rhode Island / Chemical Oceanography*

Poly- and perfluoroalkyl substances (PFASs) are of growing concern worldwide, due to their ubiquitous presence and adverse health effects in humans and the environment. Surface waters in the northeastern United States in particular have displayed elevated concentrations of PFASs. Here we utilize microporous polyethylene (PE) tube passive samplers to gain a better understanding of the sources and spread of these contaminants. Two sampling campaigns were conducted in the fall of 2017 and summer 2018, deploying a total of seventy-two PE tube passive samplers (containing Hydrophilic-Lipophilic-Balanced sorbent) across nine sites in Narragansett Bay (RI, USA) and two wastewater treatment plant effluents. 25 PFAS compounds were measured across all sites in the passive samplers, as well as analogous water and sediment samples. Initial results suggest passive sampler concentrations ranging from 0.05-6.5 ng sampler$^{-1}$ day$^{-1}$, with sampling rates of 40 to 70 mL day$^{-1}$. Results also indicate that the PE tube samplers take up PFASs in a similar ratio as observed in water samples. This preliminary study shows strong potential for the use of the PE tube sampler for PFAS detection in aquatic environments. By using passive samplers to analyze the spatial and temporal trends of these contaminants we can better assess their longevity in water and connected environmental compartments.

### 54 Using passive samplers and biomonitoring organisms to monitor polycyclic aromatic compounds and naphthenic acids in boreal wetlands

*<u>L. Mundy</u>, Environment and Climate Change Canada / National Wildlife Research Centre; D. Schock, Keyano College; R.L. Dalton, Environment and Climate Change Canada / Department of Biology; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; T. Harner, A. Eng, Environment and Climate Change Canada / Air Quality Research Division; B. Pauli, Environment and Climate Change Canada / National Wildlife Research Centre*

Several recent studies have reported evidence that surface mining operations in northern Alberta's oil sands region contribute significantly to the deposition and accumulation of inorganic (metals) and organic contaminants (polycyclic aromatic compounds (PACs) and naphthenic acids) within the vicinity of major bitumen upgrading facilities and oil sands developments. As part of the Canada-Alberta Joint Oil Sands Monitoring Program, we are characterizing the risk of exposure of wildlife, including amphibians, to these contaminants of concern. In addition to collecting abiotic (water and sediment) and biotic samples (wood frog tadpoles, *Lithobates sylvaticus*), we have deployed an array of passive sampling devices to complement these more traditional sampling techniques. In the spring of 2017, over the course of the amphibian breeding season, we equipped boreal wetlands (n=12) situated at varying distance from oil sands mines with polyurethane foam (PUF) samplers and semipermeable membrane devices (SPMDs) to measure PACs in air and water, respectively, and with polar organic chemical integrative samplers (POCIS) to measure naphthenic acids. In general, passive sampling devices accumulated a greater degree of organic contaminants in wetlands north of Fort McMurray, Alberta that were located inside the mineable oil sands area. The data collected helps us explore the use of passive samplers to identify potential contaminant 'hot spots' and conduct spatial assessments of contaminant accumulation in northern Alberta wetlands. Further, the contaminants data generated from our passive sampler work helps us address whether specific wetland monitoring sites accumulate contaminants through atmospheric deposition versus hydrological inputs, and explore correlations between contaminants accumulating in samplers with those bioaccumulating in wood frog tadpoles. In addition, we can use extracts from the organic contaminants accumulated by the SPMDs to characterize the toxicity of PAC mixtures using sensitive in vitro bioassays.

### 55 Considerations for applying experimentally-derived sampling rates to calculate organic contaminant concentrations in water from POCIS data

*<u>D.A. Alvarez</u>, USGS-CERC / Environmental Chemistry*

The global use of the polar organic chemical integrative sampler (POCIS) to monitor waters for organic contaminants with moderate to high hydrophilicity has grown rapidly over the last decade. Their use in monitoring studies has far outpaced the research to understand the sampling kinetics which is critical to obtaining reliable estimates of water concentrations. Passive sampling devices have many uses and applications; however, the ultimate goal for any type of sampler is to accurately estimate the ambient concentrations of target analytes. For integrative samplers such as the POCIS, this requires knowledge of the chemical-specific sampling rate. Sampling rates in water have been experimentally determined for over 350 individual chemicals with pesticides and pharmaceuticals accounting for approximately 75% of these chemicals. In this presentation, the role of environmental factors such as water flow, temperature, salinity, and biofouling on the uptake of chemicals will be discussed along with the applicability of the performance reference compound (PRC) approach. The proper selection of sampling rates from the literature is key in increasing the accuracy of estimating a chemical's time-weighted average concentration in water. Considerations for how a sampling rate was determined, its comparability to a specific study, and how the estimated chemical concentrations in water may be affected will also be discussed.

**56 Passive samplers of polar compounds: Application (front-end) and science (back-end)**

*K. Booij, PaSOC*

The use of adsorption based passive samplers of polar organic compounds is still largely an academic endeavor. Their use in applied and regulatory monitoring is hindered by incomplete understanding of the mechanistic basis of these samplers. As a result it is difficult to assign uncertainty estimates to passive sampling results and to take the effects of flow velocity, temperature, and biofouling properly into account. Limited understanding also makes it difficult to assess the quality of reported sampling rates, which can be rather divergent, even for the same compound and the same sampler design. Accumulation of target compounds includes transport through the water boundary layer, the biofouling layer (if present), the membrane, and finally into the sorbent. Each of these phases can have an effect on the sampling rate. The series resistance model will be used to illustrate how the importance of each of the transport steps can be separately assessed. This allows to evaluate if the overall sampling rate is quantitatively understood, including the effects of flow, temperature, and biofouling, and including the uncertainties that are associated with these effects. If sampling rates are sufficiently understood, the model can be programmed into a user friendly calculation template for end users. If not, wider uncertainty levels need to be applied. A scheme that identifies the different roles of sampler developers (science) and end users (application) will be presented. The role of sampler developers is to establish relationships between sampling rates and flow, temperature, and biofouling, and to program this into a modeling template. End users are responsible for the chemical analysis and the measurement/estimation of temperatures, flow velocities, and biofouling, including the uncertainties in these estimates, and to feed these data into the template. The template then gives an estimate of aqueous concentrations and an uncertainty estimate of this value. The models are available. The methods are available. We can reach out to end users and make this work.

## Teaching Environmental Chemistry: Where Are We and Where Are We Going?

**57 Holistic Faculty Development for Environmental Chemistry Faculty**

*C.M. Lee, Clemson University / Environmental Engineering and Earth Sciences Department; K.A. High, Clemson University / Engineering and Science Education*

Faculty who specialize in science, technology, engineering, and mathematics (STEM) experience a variety of demands in the 21$^{st}$ century. Expectations for teaching, research, service, and leadership have increased at top research universities as well at predominantly undergraduate institutions. Traditionally faculty development programs in higher education focus on teaching and learning. But many studies in STEM education research have pointed to the lack of progress in evidence-based teaching practices being widely adopted. Environmental chemistry faculty who are engaged in either undergraduate or graduate research must often obtain funding, hire and supervise students, and maintain instrumentation and other lab equipment while also meeting teaching and service responsibilities. Our hypothesis is that increased expectations for research productivity, service responsibilities, and leadership opportunities have constrained adoption of evidence-based practices. We will present NSF-sponsored research that support our hypothesis. Results from a literature review, a national workshop conducted with STEM faculty, and interviews suggest that approaches to faculty development that considers all aspects of faculty careers will enhance teaching and learning as well as improve faculty well-being.

**58 A Community-Based Research Approach to Teaching Ecotoxicology: Building Student Competencies in Science and Civic Engagement**

*S.R. Tuberty, Appalachian State University / Biology*

In the last few decades there has been a wealth of expert evidence-based research published on the links between new pedagogy and learning, as well as psychological and cognitive ability and limitations that can inform faculty on what teaching techniques create the most skill development and measurable learning outcomes for our students. In 2008, the National Survey of Student Engagement (NSSE) published a now-familiar list of what is referred to as 'high-impact practices.' These are the college experiences that highly correlate to the most powerful learning outcomes. Among the list of ~10 practices are undergraduate research, collaborative projects, service learning & community-based learning, and capstone courses and projects. These are called 'high-impact practices' because participation in them correlates with high retention and persistence rates and because they induce student behaviors that lead to meaningful learning gains. The important student behaviors include the following: 1) Investing time and effort; 2) Interacting with faculty and peers about substantive matters; 3) Experiencing diversity; 4) Responding to more frequent feedback; 5) Reflecting and integrating learning; and 6) Discovering relevance of learning through real-world applications. Over the last ten years I have created and implemented a dual-listed capstone Ecotoxicology course (senior undergraduate/M.S. level grad) that leverages several of these 'high-impact practices.' From a combination of lectures, skill & technique focused labs (supported with external grants), experiential learning techniques, and semester-long community-based group research projects, students develop knowledge and skills related to toxicology and other STEM area careers that benefit from these transferable skill sets (e.g., pharmaceutical, sustainable development and practices, and biotechnology careers). In addition to these important outcomes, the community partners add outside the classroom real-world needs and expectations that increase student 'buy-in' and opportunity for students to increase their knowledge of civic engagement and learn about related careers in their communities and beyond.

**59 Translating Environmental Chemistry Research from the Undergraduate Lab to the High School Classroom: Operation Precipitation Collaboration**

*J. Faust, K. Miller, K. Wokosin, The College of Wooster / Chemistry; W. Breneman, Smithville High School*

The primary removal mechanism of organic matter from the atmosphere is wet deposition, which transports pollutants, alters the global nitrogen budget, and impacts human health. Furthermore, precipitation offers clues to the composition of long-lived cloud droplets, which affect global climate by scattering or absorbing incoming solar radiation. A precipitation collection program in northeast Ohio was developed in collaboration with a local high school to monitor organic contaminants in rainwater while also introducing high school students to environmental chemistry research. From fall 2017 through spring 2018, juniors in the honors-level biology course at Smithville High School learned how to prepare field blanks, avoid sample contamination, and keep detailed notes. Meanwhile, undergraduate researchers at the College of Wooster analyzed the rainwater samples with solid phase extraction (SPE) and gas chromatography-mass spectrometry (GC-MS). Notably, the pesticide metolachlor was identified in rainwater collected at all sites. At the end of the school year, an undergraduate researcher involved in the project returned to the high school to explain the analysis techniques, findings, and implications. Plans are underway to continue the collection program in the 2018-2019 academic year.

**60 Fostering environmental chemistry education through incorporation with aquatic ecology**

*S. Nutile, Penn State Univ., The Behrend College / Biology*

As aquatic environments serve as the final repository for many anthropogenically derived contaminants, the study of aquatic ecology is largely dependent upon understanding environmental science and chemistry. Abiotic factors influence contaminant exposure and response of biota existing in aquatic ecosystems, thus influencing resulting aquatic communities. As aquatic ecology largely focuses on evaluating the health, history, and future of aquatic environments through sampling macroinvertebrate communities, aquatic plants, and measuring various water quality parameters, macroinvertebrate densities, species richness and diversity, chlorophyll a, water clarity, and nutrient levels all depend heavily of current and historical land-use patterns, runoff, and contamination. Without a full complement of sampling of these various parameters and understanding of the role of environmental chemistry in dictating and influencing these measured parameters, full assessment of the health and future of aquatic habitats is not possible. As such, environmental chemistry plays an undeniable role in developing a comprehensive understanding of aquatic ecology and educators teaching these courses have an opportunity to create truly integrative course for students; highlighting the diversity of environmental science and the importance of a broad science curriculum. In the fall of 2018, undergraduate students at Penn State Erie will engage in an Aquatic Ecology course with a laboratory component designed to integrate aspects of ecology, environmental chemistry, and biology. The laboratory portion of this course will challenge students to evaluate two field sites using traditional aquatic ecology sampling methodologies, environmental analysis of contaminants, water quality parameters, and historic land-use data to generate a report assessing the current health of these systems in comparison to one another and identify the major drivers that have led to this evaluation. Ideally, this laboratory structure will deepen students understanding of topics covered in lecture and appreciation of the role of environmental chemistry and science within the biology curriculum, as well as provide evidence for educators to improve educational diversity within scientific courses. This presentation will focus on the success of this approach to date, lessons learned, student perception of the value of such an exercise, and suggested improvements on this approach for the future.

**61 Using models to integrate chemistry and biology in environmental science and engineering.**

*C.A. Ng, University of Pittsburgh / Civil & Environmental Engineering*

A persistent challenge in STEM education is the training of undergraduates in design thinking. This requires the integration of conceptual knowledge to solve ill-defined or open-ended problems typical of real-world science and engineering applications. In environmental engineering and science, challenges are intensified by the interdisciplinary depth required to solve environmental challenges—students must successfully integrate concepts from biology, chemistry, and physics, among other fields. Modeling and simulation have the potential to address these challenges, while engaging students and improving their perception of their own knowledge and skills. Through the use, revision, and construction of models, students can go beyond "rote memorization" to engage critical thinking about both the concepts involved and the students' understanding of the concepts. When model construction is done collaboratively and reflectively the process allows students to probe, revise, and refine their knowledge about objects, concepts, and complex phenomena. Here, I will discuss a series of models and modeling activities I have developed at the University of Pittsburgh for both undergraduate education and K-12 outreach and their use to improve student engagement and retention in STEM. The first is a curricular module designed for middle and high school students, which uses agent-based modeling in NetLogo to engage students in understanding chemical fate and toxic impacts in aquatic ecosystems. The model is easily extendable and can also be used to engage high school seniors and college students in "low-stakes coding" to develop their own informative models. The second and third are modeling exercises aimed at sophomore- and senior-level undergraduates in environmental engineering, and are aimed at preparing them to solve open-ended problems in Senior Design. It is hoped that this presentation will spark discussions and conversations that can lead to model development and model exchanges across diverse curricula where environmental chemistry has a role.

**62 Project-Based Learning Initiatives in Environmental Chemistry**

*J.C. D'eon, S. Joudan, University of Toronto / Chemistry; J. Faust, The College of Wooster / Chemistry; S. Baskaran, University of Toronto – Scarborough / Chemistry; S. Kavassalis, University of Toronto / Chemistry*

Over the past five years project-based learning initiatives have been implemented in several environmental chemistry classes at the University of Toronto. These projects span the University curriculum; from a second-year project that places students in the role of a science advisor to a delegation attending the 1987 meeting in Montreal, which resulted in the Montreal Protocol that controls the emission of ozone depleting chemicals; to a fourth-year lab-based project where students carry out their own environmental analysis from hypothesis to lab work to presentation and report. These projects will be discussed in terms of student learning gains and a potential increase in student engagement. The more intricate details of environmental science, such as climate data and air quality measurements, are best told using visualizations such as graphs and figures. This presentation will also describe how these environmental chemistry projects have been tailored to teach students how to read and create visualizations.

**63 Establishing a long-term monitoring program of a perfluoroalkyl acid contaminated hotspot using a senior analytical environmental laboratory course**

*S. Joudan, University of Toronto / Chemistry; A.O. De Silva, Environment and Climate Change Canada / Aquatic Contaminants Research Division; S. de Solla, Environment Canada / Ecotoxicology and Wildlife Health Division; J.C. D'eon, University of Toronto / Chemistry*

Per- and polyfluoroalkyl substances are a class of ubiquitous environmental contaminants that are used in many products and applications, including as an active component in aqueous film forming foams, which are used to extinguish fuel fires. Many contamination hotspots have been reported throughout North America and worldwide, often associated with military training sites and airports. In 2012, a perfluoroalkyl hotspot was identified in Southern Ontario, a one-hour drive from the University of Toronto. Contamination at this location was traced back to firefighter training activities at the John C. Munro International Airport. This site provides us with a unique opportunity to visit a contaminated site with our fourth-year analytical environmental chemistry course and monitor its recovery over time. We visited the site in the fall semesters of 2016 and 2017, along with a nearby background site, to collect water, sediment, invertebrates and fish samples. Over two laboratory periods students performed matrix-specific extractions and analyzed the samples for 11 perfluoroalkyl acids (PFAAs) using liquid chromatograph tandem mass spectrometry. Data was shared amongst the class. In addition to the skills of sample collection, extraction, and analysis, the learning objective of this experiment was to guide students through the process of data analysis and effective communication of results through figures and graphs. This process was facilitated by a report outline that included discussion points and relevant figures. Students received detailed feedback on their outlines related to their choice of data presentation and its effectiveness in conveying their discussion points. Most students were able to find comparisons between concentrations of the contaminants, such as the relationship between carbon chain length and environmental partitioning. This experience provided students with tools for data analysis and visualization that could be applied in the course and their future research. Overall, students gained real sampling experience, and were able to compare their results to those published in peer review journals and from previous classmates, which better represented the reality of environmental monitoring. As there are many other contaminated sites around the world, we believe this experience can be applied at many other institutions.

**64 Mentoring students in a research laboratory at an undergraduate-focused institution**

*J.K. Challis, University of Manitoba / Chemistry*

The University of Winnipeg (UW), Manitoba, Canada is predominately an undergraduate institution, often praised for its teaching, small class sizes, and accessibility; aspects of a post-secondary education sometimes lost in larger research-focused universities. However, the UW also has a strong, under-the-radar research identity that relies heavily on undergraduate students through summer research positions, directed-study credits, Honours students, and Co-op programs. This presentation will summarize my experiences training and mentoring undergraduate students in an environmental analytical chemistry laboratory. Given the short-term research stints typical for many undergraduate students, training must be efficient and study design needs to be both tractable over a summer and scalable for future students. Our approach to training and mentorship will be discussed, drawing on projects as case-studies to highlight successes, challenges, and suggestions moving forward.

## Immunotoxicology: Identifying Adverse Effects, Developing New Approaches and Confronting Existing Challenges

**65 Examining the acute immunotoxicity of oil sands process-affected water using mammalian macrophages**

*L. Fu, C. Li, D. Lillico, N. Phillips, University of Alberta / Biological Sciences; M. Gamal El-Din, University of Alberta / Civil and Environmental Engineering; M. Belosevic, J. Stafford, University of Alberta / Biological Sciences*

Research examining OSPW toxicity has focused on the naphthenic acid (NA) containing organic fraction (OSPW-OF), indicating it as the primary toxic component. In this study we used an array of in vitro cell-based assays to explore OSPW toxicity and to directly compare the toxic effects induced by whole OSPW and OSPW-OF based on their relative NA content. By examining the viability, gene expression, and functional activities of mouse macrophages, we observed that the whole OSPW was significantly more toxic at NA concentrations ranging from 10-18 mg/L, compared to OSPW-OF. Specifically, our results showed that whole OSPW had a dramatic effect on the proliferation of mammalian cells, and at the highest doses tested (i.e., 12-18 mg/L) it significantly reduced cell viability and promoted cell lysis. This caused a reduction in the total cell numbers, which was not observed after the cells were exposed to equivalent doses of OSPW-OF. At the dose of 10 mg/L NAs, whole OSPW did not significantly affect viable cell numbers but the monitoring of selected stress genes indicated that a possible mode of action for OSPW-induced toxicity includes oxidative stress and associated DNA damage. We also measured pro-inflammatory cytokine expression levels after OSPW exposures to provide important information regarding its effects on mammalian immunity. Our results showed that whole OSPW at 10 mg/L NAs exhibited differential effects on basal cytokine gene expression and cytokine secretion in resting cells. In addition, whole OSPW had variable influences on the mRNA expression and protein secretion levels in activated cells. Alternatively, exposure to the OSPW-OF at 10 mg/L NAs did not induce significant effects on basal or activated cytokine gene expression or secretion. These data suggest the presence of immunomodulatory factors within whole OSPW (possibly inorganic constituents) that selectively affect cytokine networks in immune cells. The complexity of these effects requires further investigation but our results also indicate that whole OSPW-exposed macrophages have a reduced ability to engulf bacteria, which may also translate in vivo to reduced host defense capability. Overall, these observations suggest that the immunomodulatory effects of as yet unidentified OSPW constituents are dose-dependent and they can differentially affect the cell biology of immune cells at the gene, protein, and functional levels.

**66 Evaluating Immune Competence and Chemical-Induced Immunotoxicity in Amphibians**

*M. Gallant, University of Saskatchewan / Toxicology Centre; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre*

Numerous chemicals in the aquatic environment are known to modulate immune parameters in fish and amphibians, reducing their ability to resist pathogen infection and increasing incidence of disease. This is particularly relevant for amphibians as global amphibian declines have often been attributed to disease. However, there are few well-established endpoints for immune competence assessment in amphibians, which limits studies on the functional effects of chemicals exposure to pathogen susceptibility. The aim of this research was to develop an amphibian model to that would enable us to explore the possible mechanisms of the immunotoxic effects and to evaluate amphibian immune competence in an activated immune system. We first tested a blood cell staining method that enabled leucocyte counting and partial differentiation by flow cytometry. Blood was taken from juvenile *Xenopus laevis* and incubated with the lipophilic dye, 3,3'-dipentyloxacarbocyanine iodide (DiOC5(3)). Distinct populations of lymphocytes, granulocytes and monocytes were identified by flow cytometry and the number of lymphocytes and granulocytes counted using this method was in good agreement with those counted microscopically. We then tested concentrations of lipopolysaccharide (LPS), a potent immune stimulant, that could be injected to modulate white blood cells populations and cytokine expression. Intraperitoneal injection of 0.3-3 ug/g LPS resulted in a dose-dependent decrease in lymphocyte population and increase in granulocyte and monocytes as well as an induction of inflammatory cytokine expression in the kidney. Finally, these methods will be used in a host resistance assay to determine whether short-term exposure to a known immunotoxicant, benzo[a]pyrene (B[a]P), modulates immunologic responses to an LPS-challenge. We anticipate that this work will help further assessment of immune competence in amphibians and will provide information on the immunomodulatory effects of B[a]P (and eventually other chemicals) on amphibian immunity.

**67 Proposed minimum requirements for the immunotoxicity test to assess chemically induced alteration of susceptibility to pathogen in fish**

*K. Nakayama, S. Kitamura, Ehime University / Center for Marine Environmental Studies*

Recently, alteration of susceptibility to pathogen has been selected as an endpoint to evaluate the immunotoxicity of environmental contaminants in fish. It is thought as an ideal method, since chemically-induced immunosuppression ultimately leads to spread and/or outbreak of infectious disease. For the test, several different fish species have been used as host animal, and of course, pathogen used in the experiment depends on the host fish. Therefore, the experimental methods varied among studies due to the difficulty in standardizing the test method. Because of the absence of a standardized method, the experimental infections in some studies were conducted in an inappropriate way. To avoid this and misunderstanding the results of infection test, we would like to propose minimum requirements for the immunotoxicity test based on our experience. We have been using common carp (*Cyprinus carpio*) as a host fish, and conducted the infection tests with six bacterial species to determine which species are suitable for our experiment. Among them, three species including *Aeromonas hydrophila*, *A. veronii*and *Edwardsiella tarda* caused mortality in carp, however, mortality was observed only at one- or two-day post-infection, and the survived fish were not dead by the end of experiments. Mortality observed in these experiments was probably caused by toxins produced by the infected bacteria. In these cases, even if the infected fish were exposed to a test chemical, its immunosuppressive effect are not evaluated properly. Therefore, it is better to present the time-course of mortality of host fish, which represents how the fish were dead, by toxins or by immunotoxicity. Additionally, the detection of pathogen from host is also preferred to indicate that a test compound has an immunosuppressive potential. Either reisolation of pathogen using a selective medium or (quantitative) PCR can be applicable. Our improved test method with the combination of common carp and *A. salmonicida* will be presented.

**68 The arylhydrocarbon receptor (AhR) – a mediator of immunotoxicity in fish? AhR-signaling in immune and liver cells of rainbow trout.**

*A. Moeller, University of Bern / Centre for Fish and Wildlife Health; J. Song, Ehime University / Centre for Marine Environmental Studies; A. Nakayama, University of Bern / Centre for Fish and Wildlife Health; K. Nakayama, S. Kitamura, Ehime University / Center for Marine Environmental Studies; H. Segner, University of Bern / Centre for Fish and Wildlife Health*

The ligand-activated transcription factor aryl hydrocarbon receptor (AhR) senses small chemical molecules including important environmental contaminants, such as dioxins, polychlorinated biphenyls and polyaromatic hydrocarbons. Hallmarks of AhR-mediated toxicity in vertebrates are hepatotoxicity and immunosuppression. More recent studies have shown that the AhR plays an important role in the regulation of the mammalian immune system. For teleost fish, it is known that AhR-activating xenobiotics have immunosuppressive effects, but the presence and role of the AhR in the fish immune system has not been explored yet. Here, we demonstrate that immune organs and cells of rainbow trout, *Oncorhynchus mykiss*, express transcripts of the AhR isoforms, AhR2α and AhR2β. At levels comparable to transcript levels in the trout liver. Exposure of isolated trout immune and liver cells to equipotent concentrations of the AhR ligand, benzo(a)pyrene (BaP) resulted in cell-specific gene transcription profiles. Global gene expression analysis revealed that in the liver cells BaP regulated mainly genes involved in transcription and biosynthesis processes. In contrast, in the immune cells, particularly immune-related genes were regulated by BaP exposure. Genes that were commonly regulated in both cell types included CYP1A1, CYP1A3 and sulfotransferase. The findings suggest an immunoregulatory function of AhR in teleostean fish.

**69 Conserved & Differential Transcriptional Immune Responses In Commercially & Recreationally Important Fish Species Exposed to Oil, a Pathogen, or Both**

*M.L. Rodgers, The University of Southern Mississippi / Division of Coastal Sciences; M.S. Sepulveda, Purdue University / Department of Forestry and Natural Resources; R.J. Griffitt, University of Southern Mississippi / Coastal Sciences*

Polycyclic aromatic hydrocarbons are known to produce immunotoxic effects in fish and other organisms. There are relatively few studies that directly compare immune transcriptomic responses across multiple fish species to determine conserved immune responses (both in terms of gene expression and pathway regulation) to toxicants and other stressors. Evidence for the impacts of polycyclic aromatic hydrocarbons (PAHs) on immune function in fish is contradictory, with PAH type, concentration, route of exposure, and possibly even fish species driving the differing effects. In order to further understand the conserved and differential immune responses to PAHs in various fish species, three commercially and recreationally important fish species in the Gulf of Mexico were used: juvenile red snapper (*Lutjanus campechanus*), Atlantic croaker (*Micropogonias undulatus*), and red drum (*Sciaenops ocellatus*). All three species (snapper, croaker, and drum) were exposed to high energy water accommodated fractions of oil for 7 days, then exposed to the known fish pathogen V. anguillarum for one hour, followed by an additional 24 hours of oil exposure (8 days total). Upon completion of the experiment, spleens were removed from all fish and RNAseq and pathway analyses were performed to examine regulation of immune-related genes and their networks. Previous research in our lab with southern flounder (*Paralichthys lethostigma*) using a similar experimental approach found that oil alone caused suppression of immune-related genes such as irf8 and gata3 in the liver, and that exposure to V. anguillarum alone induced a different suite of immune genes, with upregulation generally occurring rather than suppression. In addition, previous research in our lab on adult sheepshead minnows (*Cyprinodon variegatus*) revealed that exposure to oil impacted innate immune pathways (for example, those related to macrophage function), and to a lesser extent adaptive immune pathways (for example, those related to B cell function). However, the flounder and sheepshead minnow RNAseq was performed on liver samples. The spleens of the three species herein present a unique opportunity to focus on an immune organ to fully understand the impacts that oil, a pathogen, or both together, have on immune genes and pathways in fish, and how these genes and pathways are either conserved or differ from one another.

**70 Immunomodulation in adult largemouth bass (*Micropterus salmoides*) following seasonal exposure to environmentally relevant contaminants and mixtures**

*L.R. Iwanowicz, United States Geological Survey / Leetown Science Center; J.K. Leet, C.A. Richter, R.W. Gale, D.E. Tillitt, US Geological Survey / Columbia Environmental Research Center*

Disease outbreaks, skin lesions, fish kill events, and reproductive abnormalities have been observed in wild populations of Centrarchids in the Chesapeake Bay watershed. Occurrence of synthetic and natural hormones from wastewater treatment plants and livestock operations, pesticides from agricultural lands, and phytoestrogens have been implicated as potential causes of these adverse effects. Our objective was to investigate possible immunomodulation in adult largemouth bass (*Micropterus salmoides*) in response to a seasonal exposure to environmentally relevant contaminants in outdoor mesocosms. Exposures included 17alpha-ethinylestradiol (EE2; 2.4 ng/L) or a binary mixture of endocrine-active substances commonly detected in the Chesapeake Bay watershed, atrazine (5.4 μg/L) and estrone (47.9 ng/L). The 5-month exposure was conducted from July to December. Functional immune responses of anterior kidney derived leukocytes were evaluated in December at the end of the exposure period, and the following April just prior to spawning. Concentrations of EE2 and estrone in the mesocosms fell below detectable levels in December, but detectable concentrations of atrazine (2.3 μg/L) persisted at least through March. For each sampling time, anterior kidney leukocytes were isolated and grown in primary culture for the assessment of zymosan-stimulated respiratory burst and lectin-stimulated mitogenic responses. Binary mixture exposure (atrazine and estrone) led to differences in respiratory burst stimulation over time and treatment with a significantly greater response in April relative to December (Mann-Whitney; $P < 0.001$). Respiratory burst activity was significantly greater in April relative to control fish assayed in April (Kruskal-Wallis One Way on Ranks, Dunn's post hoc vs control; $P = 0.008$) for this treatment as well. There were no significant differences in responses between sexes. We observed a significantly dampened mitogenic response to PHAP (a T cell mitogen) and LPS (a B cell mitogen) in the EE2 treatment relative to control fish sampled in April. Our results demonstrate that environmentally relevant concentrations of contaminants can alter immune function in an economically important fish species.

**71 The Sexually Dimorphic Immune System: An Exploration of the Influence of Sex and Sexual Maturity Status on Immune Function and Immunotoxicity in Fish**

*M.K. Sellin Jeffries, Texas Christian University / Department of Biology*

A wide variety of abiotic and biotic factors are known to influence immune function and disease resistance. In mammals and birds, it has been well established that organism sex and sexually maturity status can influence various aspects of immunity; however, less information regarding the influence of these parameters on immunity is available for fish. This talk will provide an overview of several studies, conducted in fathead minnows (a common ecotoxicological model), that demonstrate the sexually dimorphic nature of the immune system. These studies have noted several key differences in immune function between male and female fathead minnows and between more and less sexually mature male fathead minnows. For example, studies have repeatedly shown that male fathead minnows are less able to survive infection with *Yersina ruckeri* (the bacteria responsible for enteric red mouth disease) than their female counterparts. Similarly, evidence suggests that male minnows with more prominent secondary sexual characteristics (an indicator of maturity status) are less able to resist infection than those with less prominent characteristics. The data demonstrating such differences will be outlined in detail, along with the physiological underpinnings responsible for such differences. In addition, data showing that the male and female immune systems respond differently to contaminant exposures will be discussed in an effort to demonstrate the importance of considering the sexual dimorphic nature of the immune system in the design and interpretation of immunotoxicity studies.

**72 Understanding molecular mechanisms of action in immunotoxicology for ecological risk assessment through the use of adverse outcome pathway analysis**

*C.D. Rice, Clemson University / Biological Sciences; M.L. Rodgers, The University of Southern Mississippi / Division of Coastal Sciences*

Considerable evidence demonstrates the adverse effect of immune-compromise, whether stemming from inherited primary immunodeficiency, or acquired secondary immunodeficiency, such as chemical induced immunotoxicity or disrupted neuroendocrine-immune interactions leading to stress. The possible adverse outcome from these immune dysfunction(s) is increased susceptibility to pathogens, and possibly death, or even chronic inflammation. From this point, one can intuit the effects of reduced survival in terms of local population size, and the resulting negative impact on community structure and function – not to mention the possible spread of pathogens throughout the ecological system. This thought process should, in principle, be applicable to adverse outcome analysis (AOA) for use in determining the ecological risk associated with immunodeficiency as a result of exposure to contaminants. However, unlike endocrine disruption AOA for reproductive toxicants, in which the basic tenants of reproductive anatomy and physiology (A&P) are fairly consistent across fish taxa, the immune system A&P can vary. As an example, the A&P of killifish, rainbow trout, and cod immune systems are different. In addition, unlike other physiological systems, parenchymal cells of the immune system continually traffic from primary lymphoid organs throughout the organism in search of pathogens concentrated within the secondary lymphoid organs. Thus, immunocompetent cells may have a different exposure history to contaminants compared to localized cells of other physiological systems. For ecological risk assessment using AOA, any possible ecological effect of immune-compromise needs to be linked to one or more molecular initiating events (MIE), and one or more subsequent key events. Currently, we know more about the key events following exposure to immunotoxicants than the MIE. Therefore, we need to identify MIE specific to immune function(s) that could be consistently applied to specific individual, classes, or combination of contaminants. The question remains – is this possible? Moving forward, the aquatic immunotoxicology community needs to take a more collaboratively focused approach, and deep genomics to identify candidate genes targeted by MIE will no doubt be important. For environmental immunotoxicology to have its place in ecological risk assessment, focused workshops on how to incorporate AOA are needed at both the National and International level.

## Per- and Polyfluoroalkyl Substances: Recent Advances and Future Directions – Part 1

**73 Qualitative and quantitative screening of the bioaccumulative potential of PFASs in aqueous film forming foam using human serum albumin**

*W. Li, University of California Davis; T.M. Young, H.N. Bischel, University of California Davis / Civil and Environmental Engineering*

Aqueous film forming foams (AFFF) developed in the 1960s by the United States Navy and the 3M Company have been widely used and contain poly- and perfluoroalkyl substances (PFASs). Although multiple C8-PFASs (e.g., PFOS and PFOA) have been phased out of production due to toxicity, persistence in the environment and bioaccumulative potential, PFASs with similar structures such as 8:2 FTOH continue to serve industrial needs. Due to the large number of commercially available and environmentally detected PFASs, the bioaccumulative potential of PFASs used to replace legacy structures is difficult to assess. Further, the current EPA reference method for PFAS detection was designed based on a limited number of PFASs. In this study, a comprehensive PFAS screening library and HPLC-Qtof-MS method was developed to qualify and quantify PFASs in AFFF. The blood protein, human serum albumin (HSA), was then exposed to a series of AFFF dilutions using equilibrium dialysis to screen for preferential associations of specific PFASs with the model protein. A broad spectrum of PFASs, including C4-PFASs, identified in AFFF preferentially associated with HSA, suggesting a potential for bioaccumulation. Binding was not linearly correlated with the concentration of PFASs in AFFF, further implying the possibility of high binding affinity at specific sites. Preliminary results indicated that after precipitation of the protein and removal of all free PFASs in solution, the hydrolyzed HSA pellet contained strongly bound PFOS and PFHpS. Further analysis using $^{19}$F NMR and molecular docking tools is underway to evaluate mechanisms of observed protein-ligand interactions and the potential for covalent binding of PFAS with HSA. The combination of experimental and modeling techniques applied is expected to provide value in rapidly assessing the bioaccumulative potential of emerging PFASs in commercial products.

**74 Immunotoxicological Findings of an Aqueous Film-Forming Foam Formulation**

*C. Ward, Q. Hu, J.C. DeWitt, East Carolina University / Pharmacology and Toxicology*

Aqueous film-forming foams (AFFFs) are mixtures of per- and polyfluoroalkyl substances (PFASs) used extensively as fire suppressants. While several PFASs, have been classified as immune hazards to humans, few studies have evaluated the effects of AFFF exposure in vertebrate models. We hypothesized that oral exposure to AFFF, like single PFASs, would suppress the T cell-dependent antibody response (TDAR) and induce peroxisome proliferation, a biomarker of exposure. Adult female and male C57BL/6 mice were given AFFF (0, 1.88, 3.75, 7.5, 10 mg/kg or 7.5 mg/kg perfluorooctanoic acid as a positive control) via gavage for 10 days. Body weights were collected daily for 15 days and urine was collected prior to the first gavage, and 48 hours, 72 hours, 5 days, 10 days, and 16 days after the first gavage. One day after dosing ended, mice were immunized with sheep red blood cells to elicit the antigen-specific IgM antibody response. Five days after dosing ended, blood/sera and organs were collected and frozen for additional analyses. Spleens were immediately prepared for enumeration of B and T cell populations by flow cytometry, liver peroxisome proliferation was determined from frozen liver samples, and TDAR was determined by ELISA. Body weights of males exposed to 7.5 and 10 mg/kg of AFFF were statistically ($P < 0.0007$) reduced by about 15%, on average, compared to the 0 mg/kg group; female body weights did not differ by dose. Relative liver weights were statistically ($P < 0.0001$) increased 50-200% in males and 37.5-193% in females relative to the 0 mg/kg group. Liver peroxisome proliferation was increased 2- to 12-fold in all dose groups relative to the 0 mg/kg group. Spleen cellularity and splenic lymphocyte subpopulations did not differ by dose. The TDAR was suppressed 18.8% and 11.1% in males and 12.6% and 16.5% in females by exposure to 7.5 and 10 mg/kg of AFFF, respectively, relative to the 0 mg/kg group. We concluded that this PFAS mixture is more potent than single compounds, i.e., PFOA alone, at increasing liver weight, inducing peroxisome proliferation, and suppressing the TDAR and males appear to be more sensitive to effects of AFFF exposure than females for most endpoints evaluated. Additional studies are warranted to determine the most appropriate methods for assessing the human health risks of exposure to AFFF.

**75 The Toxicology of 6:2 Fluorotelomer Sulfonate (C6F13CH2CH2SO3-, 6:2 FTSA)**

*R.C. Buck, S. Gannon, The Chemours Company / Fluoroproducts*

6:2 Fluorotelomer sulfonate, C6F13CH2CH2SO3-, 6:2 FTSA, has been reported in the environment. It may originate from its direct use or from degradation of precursor substances in the environment such as short-chain fluorotelomer surfactants used in fire-fighting formualtions. The acute aquatic toxicity to fish, invertebrates and algae have been determined. In a 90-day early life-stage rainbow trout study, the NOEC was 2.62 mg/l based on mean, measured concentrations and first day of hatching. The LOEC (lowest observed effect concentration) and MATC (maximum acceptable toxicant concentration) for the same endpoint were 4.85 and 3.56 mg/L, respectively. A guideline study (OECD TG 305) that included the addition of a dietary exposure conducted under GLP was conducted to evaluate the bioconcentration and bioaccumulation potential 6:2 FTSA. Exposure conditions included a dilution water control, 1 ug/L and 10 ug/L aqueous exposures and a 10 ug/kg dietary exposure with a 56 day uptake phase followed by a 28 day depuration phase. Tissue residues of the test substance in whole fish were evaluated at multiple time points during both study phases. The test results indicated that the bioconcentration and bioaccumulation potential of the test substance is low and substantially less than any existing regulatory triggers. Similarly, the acute oral, dermal and inhalation toxicity, genotoxicity and repeated dose toxicity in rats have been studied. This paper will present the results of these studies and compare them with study data for perfluorooctane sulfonate, $C_8F_{17}SO_3^-$, an eight perfluoroalkane sulfonate and perfluorohexane sulfonate, $C_6F_{13}SO_3^-$, a six perfluoroalkane sulfonate.

**76 Evaluating whether novel PFASs are safer alternatives with a new in silico tool**

*W. Cheng, University of Pittsburgh; C.A. Ng, University of Pittsburgh / Civil & Environmental Engineering*

Per- and polyfluoroalkyl substances (PFASs) are a diverse group of chemicals that have been widely used in industrial and consumer products for decades. Among them, long-chain perfluorinated alkyl acids are now recognized as highly persistent, bioaccumulative and toxic contaminants. Growing concern regarding their negative effects has led to a phasing out of the production of long-chain PFASs. To take their place, manufacturers have started using PFAS alternatives such as perfluoroether carboxylic acids (PFECAs) and perfluoroether sulfonic acids (PFESAs). However, very little information is available about the bioaccumulation potential and toxic effects of these replacement compounds. Given the vast number of PFASs, a rapid and reliable method to predict the behavior of these chemicals within organisms would be of great benefit. Our previously developed physiologically based pharmacokinetic (PBPK) model has shown that the interaction between PFASs and proteins such as serum albumin, liver-type fatty acid binding protein (LFABP), and organic anion transporters plays a critical role in determining the bioaccumulation of PFASs. In this study, we selected LFABP as our target protein and developed a workflow that combines molecular docking and molecular dynamics simulation approach to estimate the binding affinity of a total of fifteen legacy and alternative PFASs for two LFABPs (i.e., rat and human LFABP). The predicted results were compared with experimental data extracted from three different studies. There was good correlation between predicted free energies of binding and measured binding affinities, with the correlation coefficients being 0.96, 0.97, and 0.78 for three studies, respectively. This indicates that our method is able to rank the protein binding affinities of PFASs. Among the five novel PFASs (i.e., EEA, GenX, ADONA, F-53, and F-53B), our results suggest that EEA and ADONA are at least as strongly bound to rat LFABP as perfluoroheptanoic acid (PFHpA), and to human LFABP as perfluorooctanoic acid (PFOA); F-53 and F-53B both have similar or stronger binding affinities compared with perfluorooctane sulfonate (PFOS). This indicates that these alternatives could be as bioaccumulative as legacy PFAS and are not necessarily safer alternatives.

**77 Investigating gene expression in male and female zebrafish after perfluorooctane sulfonate (PFOS) exposure**

*M. Khazaee, C.A. Ng, University of Pittsburgh / Civil and Environmental Engineering*

Perfluorooctane sulfonate (PFOS) is a member of the anthropogenic class of per- and polyfluorinated alkyl substances (PFAS) that have been used in domestic and industrial products for more than 50 years. Many studies reported detectable concentrations of PFOS in water, sediments, humans, mammals, and fish around the world. The zebrafish (*Danio rerio*), is a small freshwater fish considered as an appropriate vertebrate model for investigating the toxicity of compounds. Previous investigations showed the tissue-specific bioaccumulation in male and female zebrafish, potentially due to interactions between PFAS and fatty acid transporters. PFAS strongly bind to proteins in plasma and other tissues like liver, such as apolipoproteins and fatty acid binding proteins (FABPs). Previous studies indicated that exposure to perfluorononanoic acid alters the expression of FABPs and peroxisome proliferator-activated receptors in both sexes of zebrafish. Therefore, this study was designed to investigate whether PFOS exposure affects the expression of genes associated with lipid metabolism (*fabp1a*, *fabp2*, and *fabp10*) and genes involved in the nervous system (*hdac6*, *chat*, and *ache*) in different tissues of both genders of zebrafish. Male and female zebrafish (n = 142) were randomly divided into three groups of control, low (0.1 mg/L), and high (1 mg/L) doses. Each group had three replicates per treatment, and ~ 16 fish per replicate. Fish were exposed to PFOS for 30 days and sampled on the $1^{st}$, $7^{th}$, $14^{th}$, and $30^{th}$ days of the experiment. Four fish from each replicate were dissected on each sampling day, and liver, heart, brain, muscle, intestine, and ovary were extracted and stored at −80 $^{o}$C for RNA extraction by real-time quantitative reverse transcription PCR (qPCR). Selecting a proper housekeeping gene is essential to maximize the PCR efficiency. Appropriate housekeeping genes for use as normalizers for qPCR should be stably expressed under different experimental conditions. To identify the most efficient housekeeping genes for our study, *tbp*, *bactin1*, *bactin2*, *mob4*, *eef1a1b*, and *ism12b* genes were evaluated. Based on the results, bactin1, bactin2, and tbp showed high efficiency and less variability, respectively. Moreover, results indicate differences in expression of genes associated with lipid metabolism and neural function, due to differences in both exposure concentration and gender.

**78 PFHxA Human Health Risks, Margin of Safety, and Comparison with PFOA**

*A. Luz, L. Tolbert, J. Anderson, P.E. Goodrum, Integral Consulting Inc.; D. Farrar, CCERT Ltd; S. Korzeniowski, FluoroCouncil / BeachEdge Consulting*

Perfluorohexanoate (PFHxA) is a short-chain perfluorinated carboxylic acid (PFCA) and a primary degradation product of the manufacturing intermediates used to produce some fluorinated polymers and fluorotelomer-based products today. The fluorochemistry industry specifically moved away from chemistries that relied on or resulted in long-chain PFCAs, switching to these shorter chain substances with improved hazard profiles. Because of the high stability of the carbon-fluorine bond, PFHxA is not expected to easily break down in the environment, and low concentrations of PFHxA have been detected in some environmental samples. The stability and environmental occurrence of PFHxA necessitates a clear understanding and communication of human health risk, including for the potentially most susceptible subpopulations due to higher exposures—infants and children. This presentation will summarize the available information on exposure and toxicity of PFHxA, and, relying on peer-reviewed, regulatory, human health toxicity values and human biomonitoring data, a corresponding margin of safety will be developed. Finally, methods for comparing properties of PFHxA and perfluorooctanoate (PFOA) will be presented. The available toxicological and kinetic data indicate that the relative potency of PFHxA is much lower than that of PFOA. The highest dose to humans that is unlikely to be associated with adverse effects differs between the two compounds by more than 5 orders of magnitude. Typical human exposure levels result in a drinking water threshold level for PFHxA that is almost 32,000 times higher than the USEPA lifetime health advisory for PFOA.

**79 Fluoropolymers: Polymers of Low Concern That Are Unique PFAS**

*B. Henry, J.P. Carlin, J.A. Hammerschmidt, W.L. Gore & Associates, Inc.; R.C. Buck, The Chemours Company / Fluoroproducts; L. Buxton, The Chemours Company; H. Fiedler, UNEP / DTIE Chemicals Branch / MTM Research Centre School of Science and Technology; J. Seed; O. Hernandez, Bergeson & Campbell*

Per- and poly-fluoroalkyl substances, PFAS, are currently the focus of researchers and regulators due to widespread presence of some PFAS (e.g., perfluorooctane sulfonate, PFOS, and perfluorooctanoic acid, PFOA) in the environment and biota, including humans. Fluoropolymers, such as polytetrafluoroethylene (PTFE), constitute a distinct class within the polymeric category of the PFAS group. Fluoropolymers are resistant to chemical, hydrolytic, oxidative, photochemical and biological degradation. They are thermally stable within their intended processing temperatures (e.g., 260°C for PTFE). Fluoropolymers have negligible residual monomer, low molecular weight oligomer, or leachable content. Fluoropolymers have high molecular weights well over 100,000 Da, are practically insoluble in water and are not mobile or subject to long-range transport in the environment. Their very high molecular weight prevents fluoropolymers from crossing the cell membrane and thus they are not bioavailable or bioaccumulative. The nontoxic nature of PTFE is supported by numerous Good Laboratory Practice (GLP) studies including acute and subchronic systemic toxicity, irritation, sensitization, local toxicity on implantation, cytotoxicity, in vitro and in vivo genotoxicity, hemolysis, complement activation, and thrombogenicity. Clinical studies of patients receiving permanently implanted PTFE-containing medical devices demonstrate no chronic toxicity or carcinogenicity, reproductive, developmental or endocrine toxicity. Fluoropolymer medical devices have been implanted in over 40 million patients for over 40 years. This poster includes fluoropolymer biocompatibility/toxicology, human clinical, and physical-chemical-thermal-biological data to show that fluoropolymers satisfy globally recognized assessment criteria to be considered as “Polymers of Low Concern” and to be recognized as being a low hazard class of PFAS. Fluoropolymers, therefore, are distinctly different from the other polymeric and non-polymeric classes of PFAS and should be separated from all other classes of PFAS for hazard assessment or regulatory actions. Grouping all classes of polymeric and non-polymeric PFAS together for restriction or regulation is not scientifically appropriate. Fluoropolymers, as polymers of low concern, are uniquely benign PFAS.

**80 Effect of sample storage on the quantitative determination of PFAS – observation of analyte interconversions during storage.**

*M. Woudneh, SGS AXYS Analytical Services Ltd; B. Chandramouli, SGS AXYS; C. Hamilton, SGS AXYS / Client Services; R. Grace, J. Cosgrove, SGS AXYS*

Sample, extract and standard stability information is critical for the accurate measurement of contaminants. In the present study, we measured the effect of sample type and storage temperature on the stability of per- and polyfluorinated alkyl substances (PFAS)in water. Spiked reagent water, surface water, and effluent samples were stored in HDPE container at +20?C, 4?C, and -20?C over a period of up to 100 days. C4-C14 perfluorinated carboxylates, C4-C10 and C12 perfluorinated sulfonates, 4:2, 6:2 and 8:2 fluorotelomer sulfonates, three perfluorooctane sulfonamides (PFOSA, N-MeFOSA, N-EtFOSA), two perfluorooctane sulfonamide ethanols (N-MeFOSE and N-EtFOSE), and two perfluorooctane sulfonamideacetic acids ((N-MeFOSAA and EtFOSAA) were included in the study. Overall, perfluorinated carboxylates, sulfonates, and fluorotelomer sulfonates did not display significant concentration changes in reagent water, surface water and effluent samples over the study period and at all temperature conditions. There was a steady increase in the concentrations of NMeFOSAA and NEtFOSAA in both surface water and effluent samples over the study period at +20?C, and 4?C. The behavior was not observed in reagent water samples and indicated the impact of sample matrix on the stability of polyfluorinated compounds during storage. In addition, the increases in concentrations of NMeFOSAA and NEtFOSAA tracked the decreases in the concentrations of N-MeFOSE and N-MeFOSA, N-EtFOSE and N-EtFOSA respectively indicating potential for analyte conversion during sample storage. This is the first time such analyte conversion is reported in samples under storage and demonstrates the importance of assessing stability of polyfluorinated compounds in environmentally relevant matrices.

## Bayesian Network Applications for Environmental Risk Assessment and Management

**81 An Introduction to Bayesian Networks for Environmental Risk Assessment and Management**

*W.G. Landis, Western Washington University / Institute of Environmental Toxicology; J.F. Carriger, Jr., USEPA / National Risk Management Research Laboratory*

Bayesian networks (BNs, also known as Bayesian belief networks) are a means of describing cause and effect using directed acyclic graphs where the interactions between the nodes are described using conditional probability tables. That is a way of saying that that there are nodes (steps in a cause-effect model), which are connected by lines of influence, and the interactions are described using probability tables that take into account all possible combinations of inputs to generate the probability distributions for each possible outcome. Bayesian networks inherently incorporate uncertainty and can use wide varieties of data, from precise determinations of molecular interactions to expert elicitation. B. Marcot was an early pioneer in the use of BNs for environmental management for the US Forest Service. The use of BNs in ecological risk assessment began in the early 2000s pioneered by B. Hart and C. Pollino in Australia. Since 2010 a number of papers have been published on the use of BNs to evaluate management options, to evaluate risk, to provide a more quantitative framework for the relative risk model, and to become a part of adaptive management. This session includes presentations by developers and users of Bayesian networks to estimate risk, calculate the outcomes of management alternatives and the use of such techniques to make policy decisions. Likely topics include estimating the risk due to contaminants, invasive species, oil spills, climate change, the inclusion of adverse outcome pathways as part of ecological risk assessment, and the evaluation of management alternatives. The use of BNs as part of developing long-term policy in collaboration with managers and stakeholders will be presented. The big questions are now where do we go from here and the adoption of BNs to advance ecological risk assessment and management.

**82 Data-Informed City-Level Adaptive Management: A Bayesian Approach for Quantifying Climate Change Risk and Resilience in Charleston, SC**

*M. Cains, D. Henshel, Indiana University / Public and Environmental Affairs; W.G. Landis, Western Washington University / Institute of Environmental Toxicology*

The greater Charleston Harbor region is highly susceptible to the projected impacts of climate change due to low lying geography, a disparate socioeconomic spectrum, and invaluable ecosystem services. In an effort to become climate change resilient, the City of Charleston, SC is conducting an "all hazards" vulnerability assessment to geospatially identify populations and assets (e.g. economic, historic, and ecosystem services) vulnerable to sea level rise, precipitation extremes, extreme heat, and storm surges. The presented research highlights the use of the Bayesian Network-Relative Risk Model as a means to quantify climate change risk and resilience beyond a semi-quantitative vulnerability assessment. The BN-RRM is parameterized using inherent community knowledge gathered via facilitated workshops and the Multi-level Parameterization Risk Assessment Framework. The parameterization framework breaks down a primary stressor (e.g. climate change) into its secondary (e.g. sea level rise, extreme precipitation) and tertiary (e.g. nuisance flooding, habitat alteration) stressors. Tertiary climate change stressors are consequences of the secondary stressors, just as the secondary stressors are regional consequences of global climate change. As an adaptation of the BN-RRM, the presented multi-stressor model incorporates resilience parameters as control factors that modulate how risk is carried through the model. These control factors serve as "filters" controlling the degree of exposure to stressors and intensity of effects. Control factors represent resilience characteristics (i.e. plan/prepare, absorb, recover, and adapt), management practices, and/or personal actions that, when properly implemented, reduce exposure to a stressor and/or the impact of an effect, which effectively reduces risk to the assessed endpoint. If managers (e.g. city, emergency, or environmental managers) are to manage within a complex system, their decisions should be informed by assessments that, at the very least, attempt to evaluate the system as a whole. While single stressor risk assessments are inherently easier to conduct, management decisions based on one or a suite of single stressor risk assessments may not be effective due neglected sources of compounding risk. The BN-RRM approach provides the City of Charleston with a decision support tool to systematically quantify the multi-stressor risk-resilience relationship, an otherwise emergent property of a complex system.

**83 Quantification of AOPs by Bayesian network modelling: Linking chemical exposure to adverse outcomes in Lemna minor populations**

*J. Moe, Norwegian Institute for Water Research (NIVA) / Section for Catchment Processes; W.G. Landis, Western Washington University / Institute of Environmental Toxicology; K. Tollefsen, L. Xie, NIVA Norwegian Institute for Water Research / Environmental Toxicology; N. Kotamäki, Finnish Environment Institute SYKE; Y. Song, NIVA Norwegian Institute for Water Research / Environmental Toxicology*

Adverse Outcome Pathways (AOPs) has gained international recognition as a systematic approach for capturing existing toxicological knowledge to transparently link mechanistic data to toxicity endpoints. Nevertheless, qualitative AOPs are not directly suitable for quantitative risk assessment. Quantitative AOPs (qAOP) should define the relationships underlying transition from one KE to the next sufficiently well to allow quantitative prediction of the probability or severity of the AO occurring for a given activation of the MIE. We have developed a Bayesian Network (BN) model to quantify a recently proposed AOP, which links the mode of action of the model respiratory and photosynthesis uncoupler 3,5-dichlorophenol (DCP) to adverse outcomes in the aquatic plant *Lemna minor.* The BN model is based on data from a laboratory experiment exposing *L. minor* to DCP in 8 concentrations with 3 replicates. The measured response variables include OXPHOS (oxidative phosphorylation), ROS (reactive oxygen species), ETR (electron transfer rate), Fv/Fm (maximum quantum yield of photosystem II), LPO (lipid peroxidation) and number of fronds (leaves). The proposed AOP is a network consisting of three chains with the same chemical stressor (DCP) and AO (fronds number). All AOP components are defined in the BN as nodes with discrete states. Each node is quantified by a probability distribution across these states, and the causal links (Key Event Relationships) are quantified as conditional probability tables (CPTs). The probability distributions of the CPTs are obtained from dose-response regression models fitted to the experimental data and their estimated uncertainty. The BN was tested by examining the response of the nodes to different concentrations of DCP and observing the exposure-response relationships. All KEs and AOs of the BN responded to increasing the MIE (DCP concentration) in accordance with the conceptual model. Increasing DCP resulted in monotonous decrease in fronds number in all three pathways. Sensitivity analysis indicated that the pathway OXPHOS → ETR → fronds number was the most sensitive to changes in DCP concentration, while the pathway ROS → LPO → Fronds no. was the least sensitive to the DCP concentration. Planned further developments of this BN model include linking the AO to population-level endpoints with regulatory relevance, and linking the chemical stressor to an Aggregate Exposure Pathway.

**84 Integrating climate change stressors and human health and well-being endpoints into a Bayesian network relative risk model**

*E. Lawerence, A.J. Markiewicz, W.G. Landis, Western Washington University / Institute of Environmental Toxicology*

Climate change is expected to have widespread impacts on ecosystem services in the Salish Sea. In this research, we focused on the question of how stressors generated by climate change affect contaminant toxicity to species in the Skagit River Watershed. Specifically we assessed how those combined effects potentially influence risks to the river's ecosystem services that, in turn, impact human health and well-being. To answer this question, we are conducted an ecological risk assessment using the Bayesian network relative risk model (BN-RRM). It is a quantitative, probability-based model that calculates complex relationships between ecological variables to provide estimates of risk to valued receptors (endpoints). The Skagit River Watershed contains important habitats for native salmon species and bald eagles (*Haliaeetus leucocephalus*). These species provide numerous ecological, economic, cultural, and spiritual services to humans. Its floodplains also provide fertile, highly productive croplands, making it an important agricultural center in the region. Pesticide use on croplands in the watershed pose potential threats to these non-target species that may increase in severity with climate change. Increasing water temperature, decreasing dissolved oxygen levels, and changes in seawater pH are of particular concern, as are changing river and stream flows, increasing storm event frequency and intensity, and sea level rise. These stressors have potential to impact human health and well-being endpoints such as human well-being, water quality, salmon fisheries, tribal cultural and community health indicators, recreation areas, tourism, agriculture, boating, fishing, and shellfish harvesting. The BN-RRM enables us to calculate the risks posed by various stressors on these select endpoints in the Skagit River watershed due to climate change. The BN-RRM can also serve as a useful tool for resource managers and decision-makers as part of an adaptive management process and to direct future research efforts in the watershed, as well as in other watersheds in the Salish Sea region.

**85 A regional scale ecological risk framework for environmental flow evaluations.**

*G.C. O'Brien, University of KwaZulu-Natal / School of Life Sciences; C. Dickens, International Water Management Institute; V. Wepener, North-West University / Unit for Environmental Science and Management; W.G. Landis, Western Washington University / Institute of Environmental Toxicology*

Environmental Flow (E-flow) frameworks advocate holistic, regional scale, probabilistic E-flow assessments that consider flow and non-flow drivers of change in a socio-ecological context as best practice. Regional Scale ecological risk assessments of multiple stressors to social and ecological endpoints, that address ecosystem dynamism, have been undertaken internationally at different spatial scales using the relative-risk model since the mid 1990's. With the recent incorporation of Bayesian belief networks into the relative-risk model, a robust regional scale ecological risk assessment approach is available that can contribute to achieving the best practice recommendations of E-flow frameworks. PROBFLO is a holistic E-flow assessment method that incorporates the relative-risk model and Bayesian belief networks (BN-RRM) into a transparent probabilistic modelling tool that addresses uncertainty explicitly. PROBFLO has been developed to evaluate the socio-ecological consequences of historical, current and future water resource use scenarios and generate E-flow requirements on regional scales spatial scales. The approach has been implemented in two regional scale case studies in Africa where its flexibility and functionality has been demonstrated. In both case studies the evidence based outcomes facilitated informed environmental management decision making, with trade-off considerations in the context of social and ecological aspirations. This paper presents the PROBFLO approach as applied to the Senqu River catchment in Lesotho and further developments and application in the Mara River catchment in Kenya and Tanzania. The ten BN-RRM procedural steps incorporated in PROBFLO are demonstrated with examples from both case studies. PROBFLO can contribute to the adaptive management of water resources, and contribute to the allocation of resources for sustainable use of resources and address protection requirements.

**86 Multiple Stressor Ecological Risk Assessment of a Highly Regulated Water Catchment in the Context of South African Legislation**

*I. Govender, Durban University of Technology / Horticulture; G.C. O'Brien, University of KwaZulu-Natal / School of Life Sciences; T.A. Stenström, Durban University of Technology; G. Jewitt, University of KwaZuluNatal / Centre for Water Resources Research*

The uMngeni River, is a highly regulated, socio-ecologically important catchment in KwaZulu-Natal, South Africa, where more than four million people live and depend on the system. Increasing urban growth and economic investment in an area of strategic national importance, has resulted in increasing demands for water supply to sustain social and economic development. Land use in this catchment includes rural communities, high intensive agriculture, forest plantations, industries and urban centres. National legislation requires the achievement of a balance between water provision for all water users and protection of water resources. The Bayesian Network Relative Risk Model (BN-RRM) is used to model multiple stressors in this dynamic catchment to four endpoints: two ecological endpoints (Maintenance of river and riparian connectivity, Control of alien invasive plant species), and two social endpoints (Maintain Basic Human Needs and Maintain ecosystem for recreation and tourism).
The study area was delineated into six risk regions linked to location of impoundments. The endpoints are measured against the legislated water resource quality objectives (RQOs) for the river resources, to determine if the RQOs are achievable under the current scenario and alternative scenarios. This case study integrates local hydrology data, water quality data, impoundment information and data, water use statistics and land use information, to generate risk profiles for the selected endpoints. This is a probabilistic framework, that adopts a holistic approach to evaluate trade-offs between selected ecological and social endpoints within the context of legislation. Results under the current situation indicate that there are differences in risks to the selected socio-ecological endpoints in each risk region, which are influenced by varying environmental conditions in each risk region. Land use and drought conditions are significant considerations for habitat quality and habitat availability. Future scenarios such as increased urban growth and climate change, indicate regional variations associated with a synergy of various stressors. Risk profiles for the aforementioned future scenarios suggest that achieving the legislated RQOs may be challenging, unless there are specific interventions.

**87 Combining Bayesian networks and conceptual models for Superfund remediation support**

*J.F. Carriger, Jr., USEPA / National Risk Management Research Laboratory; R.A. Parker, US Environmental Protection Agency / National Risk Management Research Laboratory*

Conceptual models play a central role in Superfund remediation. They are used as a communication tool and a platform for quantitative models. Bayesian networks offer many opportunities for supporting conceptual and quantitative modeling in Superfund remediation. However, their application to Superfund risk assessments and management is still rare. A framework will be presented that combines Bayesian network knowledge engineering and development with requirements and recommendations for Superfund conceptual models. We call the resulting products conceptual Bayesian networks (CBNs). A development process for Superfund CBNs will be introduced that can support all phases of site investigation and cleanup. Learning is incorporated into the process for updating knowledge of the model structural components and connections as new data and understanding becomes available. Inferences to support decision making with a CBN will be presented including causal pathway analysis from sources of stressors to receptors of concern and capabilities for examining the causal influence of remediation interventions in breaking exposure pathways. The CBN process is designed for adaptability to multiple sites and stressor-types as well as comprehensiveness for adequately incorporating required legal and scientific guidance for site assessments. Components and connections that are broadly transferrable will be shown. The focus of the presentation is on the qualitative side of Bayesian network development and inferences, which is necessary for subsequently developing quantitative models. The potential value added of a CBN for quantitative risk assessments will be demonstrated. The flexibility of CBNs allows adaptation across all phases of Superfund assessments and can support management decision making, uncertainty evaluation, and communication from the structural and quantitative capabilities of Bayesian networks.

**88 Relative Risk Models Using Bayesian Networks: Application, Communication and Regulatory Use**

*S. Thakali, A. Miano, J. Collins, AECOM; C. Mancini, AECOM / Environment Health; R.G. Stahl, M.R. Liberati, E.I. DuPont de Nemours and Company / Corp Remediation*

Historical mercury release occurred on the South River, Virginia, between 1929 and 1950 from a former DuPont facility. Legacy mercury in the potentially impacted areas has been the subject of numerous studies over the last four decades. The South River Science Team (SRST), a multi-stakeholder group, was established in 2001 to investigate the potential impacts to the aquatic and riparian terrestrial systems along the South River and a portion of the South Fork Shenandoah River. A model framework was developed with input from the SRST based on Bayesian Network-Relative Risk Models (BN-RRMs). The BN-RRMs for two ecological receptors (i.e., Smallmouth Bass and Carolina Wren) and ecosystem services (i.e., Swimming, Boating, and Fishing) were applied to support risk and remedial decisions for the South River. These BN-RRMs integrated contributory risk factors and quantified overall risk scores for five contiguous risk regions, including an upstream reference region located approximately 10 miles upstream from the former DuPont facility, as well as portions of the South River and the South Fork Shenandoah River extending 30 miles downstream of the former DuPont facility. The risk regions were configured to be as consistent as possible with natural breaks based on land use and hydrogeology, the upstream-to-downstream remedial approach and existing short- and long-term monitoring stations. The BN-RRMs were applied primarily to evaluate: 1) the relative importance of contributory factors besides mercury and 2) "what if" scenarios regarding anticipated system response to the remedial approach/extent. The use of the select BN-RRMs was realized as intended, simply as a tool to generate one of several lines of evidence. The modelling results showed that factors other than mercury contributed to overall risks, relative risks varied among the risk regions, and planned remedial measures would achieve varying degrees of risk mitigation among the risk regions. As such, the use of BN-RRMs facilitated communication of a holistic approach to risk evaluation and provided a predictive capability to support adaptive management approaches to remedial decisions. In this presentation, the following aspects of the models and their applications will be shared: 1) modeling framework, 2) public and regulatory receptiveness; 3) transparency, limitation, and communication; and 4) overall utility in a regulatory context.

# Per- and Polyfluoroalkyl Substances: Recent Advances and Future Directions – Part 2

### 89 Measurement, occurrence and applications of GenX (HFPO-DA), a replacement for PFOA

*B. Chandramouli, SGS AXYS; M. Woudneh, SGS AXYS Analytical Services Ltd; S. Hewage, J. Cosgrove, SGS AXYS*

Per-and polyfluorinated alkyl substances (PFAS) are a focus of study due to widespread use, prevalence in the environment, and bioaccumulation and health effects of longer chain perfluoroalkyl acids (PFAAs) such as PFOA and PFOS. Phaseout of PFOS and PFOA, and their replacement by newer chemistry means that these "novel" PFAS are being detected in the environment. For example, PFOA in fluoropolymer manufacture is being replaced with a diverse set of per-/polyfluoroether carboxylic acids including GenX (2,3,3,3-Tetrafluoro-2-(1,1,2,2,3,3,3-heptafluoropropoxy) propanoic acid or HFPO-DA) , ADONA (3H-perfluoro-3-[(3-methoxy-propoxy)propanoic acid]), PMPA (tetrafluoro-2-( hexafluoro-2-(trifluoromethoxy)propoxy]-propanoate) and others. Chrome plating alternatives for PFOS include F-53B (6:2 chlorinated polyfluorinated ether sulfonate) and others. More data is needed on occurrence, fate, transport and health effects of these replacment PFAS in order to inform risk asessment. Of these, GenX is under increased scrutiny, especially in North America after the discovery of HFPO-DA in watersheds adjacent to a fluoropolymer manufacturing facility in North Carolina[1]. There is a great need for increased monitoring of HFPO-DA in the environment, occurrence and bioaccumulation in fish/wildlife, and fate in sewage treatment. The use of oxidative assays such as the total oxidizable precursor (TOP) assay can also shed light on ultimate environmental fate. This study reviews GenX use, analytical methods, occurrence in the ecosystem and in wastewater treatment plants, and results from TOP analysis. Methods for HFPO-DA were developed and validated in water and soil using isotope dilution LC-MS/MS. 250mL aqueous samples were fortified with $^{13}C_3$-HFPO-DA, extracted using weak anion exchange (WAX), and concentrated prior to analysis. 5g soil samples were fortified with $^{13}C_3$-HFPO-DA, extracted using methanol, cleaned up using WAX, and concentrated. Extracts were analysed using a Waters Acquity UPLC interfaced with a Waters TQ-S tandem mass spectrometer. Validation in aqueous samples resulted in a recovery of 97% with an RSD of 5% and method detection limits < 5 ng/L. Solid samples showed a recovery of 111% with an RSD of 15%, and method detection limits < 0.5 ng/g. Data on occurrence in the ecosystem and wastewater treatment plants, and fate of HFPO-DA in the TOP assay will be presented. References Strynar, M., Dagnino, S. et al. (2015). Environ. Sci. Technol. 49, 11622–11630.

### 90 Aerobic Biodegradation of Short-Chain Fluorotelomer Based Methacrylate Polymers Is Not A Significant Source Of Environmental Short-Chain PFCAs

*W. Knaup, Archroma Germany GmbH; C. Mislin, Archroma Management GmbH; S. Fiebig, H. Maischak, S. Goller, Noack Laboratorien GmbH*

Short-chain fluorotelomer based methacrylate polymers are a class of side-chain fluorinated polymers used for a variety of commercial applications, including some food contact packaging materials and treatment of carpet and rug fibers. It has been suggested that the degradation of these polymers could be a source of short-chain perfluoroalkyl carboxylates (PFCAs) to the environment and there is increasing concern regarding the stability of these polymers in the environment. Per USEPA requirements under the Toxic Substances Control Act, the aerobic biodegradation of a specific fluorotelomer-based methacrylate polymer, identified as "Nuva RP2116 GA", was evaluated following USEPA OPPTS 835.4100 (2008) and OECD 307 Aerobic and AnaerobicTransformation in Soil (2002) guidelines over ~15 months in four natural soil conditions. Potential degradation products were selected for measurement under direction from USEPA and included fluorotelomer alcohols 5-2s FTOH and 6:2 FTOH (by GCMS/MS analysis) and perfluoropentanoic acid (PFPeA), perfluorohexanoic acid (PFHxA), perfluoroheptanoic acid, C6-2 fluorotelomer carboxylic acid, C6-2 fluorotelomer unsaturated carboxylic acid, and C5-3 fluorotelomer carboxylic acid (by LC-MS/MS analysis).6-2 FTOH, which is considered to be the primary initial metabolite associated with the biological transformation as well as a potential low level impurity, was rapidly transformed in all four soils and remained at a low levels in the test material. Kinetic parameter estimates include conditions in which a plausible fraction of 6-2 FTOH equivalents may have been present as an impurity in the test substance. The dominant intermediate metabolite, 5-2s FTOH, was observed mainly during the first 3 to 6 months. The dominant terminal metabolites were PFPeA and PFHxA. At the conclusion of the test the sum of all potential degradation products was less than 0.04% of 6-2 FTOH equivalents in all four soils. A first order kinetic model applied to residual 6-2 FTOH equivalents measured in the initial period of degradation (prior to reaching a plateau) supports estimated half-lives of thousands of years in soil. Transformation rates would be even slower in soils with less aerobic biological activity and studies under anaerobic conditions are underway. Aerobic transformation in soil of short-chain fluorotelomer based methacrylate polymers are, therefore, not likely a significant source of short-chain PFCAs currently detected in the environment.

### 91 The sorption of PFOA, PFOS and PFHxS in soils

*E. Knight, University of Adelaide / Soil Science; L. Janik, D. Navarro, R.S. Kookana, CSIRO / Land and Water; M. McLaughlin, University of Adelaide / University of Adelaide and CSIRO Land and Water*

Emerging contaminants, such as perfluorinated alkyl substances (PFASs) are of increasing concern in the environment due to their stability, longevity, bioaccumulation and potential toxicity. These attributes have led perfluorooctanesulphonic acid (PFOS) to be placed on the Stockholm Convention for persistent organic pollutants (POPs) and perfluorooctanoic acid (PFOA) and perlfuorohexane sulphonate (PFHxS) are currently being considered. Concentrations of PFASs in soils vary greatly – from pg/kg to mg/kg – but are particularly high in contaminated sites such as fire-fighting training grounds and airfields (mg/kg). Once exposed in the environment their behaviour and interactions with soil are not completely understood. Small scale studies, generally comprising < 10 soils, in terrestrial systems have indicated that there are relationships between retention of PFASs and soil organic matter content, clay content and iron oxides. In this study PFOS, PFOA and PFHxS were tested for their sorption capacity to 170 characteristically different soils from an Australian national soil archive. The soils were randomly selected to provide a wide range of properties such as pH, total carbon content, cation exchange capacity and clay content. The aims of this study were to: establish soil-water partitioning coefficients ($K_d$) for a wide range of soils; establish which soil characteristics control the binding of these PFASs; and develop simple rapid methods to predict PFAS partitioning in soils. The use of simple linear regression, multiple linear regression (MLR) and partial least squares regression in conjunction with soil spectra from diffuse reflectance mid-infrared Fourier transform spectroscopy (MIR-PLSR) was used to model the sorption of PFOS, PFOA and PFHxS in the soils. Soil organic carbon content was not adequate to explain partitioning of these chemicals in soils, indicating that normalising partition coefficients to organic carbon content only, is less effective than considering a wider range of soil properties. The MIR-PLSR modelling technique was found to be an extremely rapid, cheap and robust method to predict partitioning of these compounds across a wide range of soils.

**92 Novel Fluorinated Polymer Surfactants in Biosolids From Wastewater Treatment Plants Across Canada and Source Linkages to Biosolid-Augmented Soils**

*R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; S. Chu, S. Smyth, Environment and Climate Change Canada*

Side-chain fluorinated polymer surfactants are per-/poly-fluoroalkyl substances (PFASs) and are the main components of fabric protector sprays and used on furniture and textiles. These fluorinated polymers may be a source, as a result of their degradation and subsequent formation, of perfluorinated carboxylic acids (PFCAs) and perfluorinated alkane-sulfonates (PFSAs). We have shown that available fluorinated surfactant products, pre- and post-2002 Scotchgard fabric protector (3M Company), can be metabolically degraded in an in vitro assay based on Wistar-Han rats liver microsomes, to metabolites containing the N-methyl-perfluorobutanesulfonyl (S1) and N-methyl-perfluoroctanesulfonyl (S2) chemical moieties, respectively, which are precursors to perfluoro-1-octane sulfonamide (FOSA) and perfluoro-1-butane sulfonamide (FBSA), respectively. Studies have shown the presence of various PFASs including S1 and S2 in agricultural soils in southern Ontario, Canada, where wastewater treatment plant (WWTP) sourced biosolid application had occurred and not occurred. The main side-chain fluorinated polymer components in pre-Scotchgard (S1) and post-Scotchgard (S2) were shown to be source linked to the biosolid application. S1 was detected in 100% of the soil samples from biosolid-augmented agricultural sites at a mean concentration of 236 ng/g d.w., and at concentrations much greater than in soil samples from the two sites where no biosolid had been applied (mean concentrations of 3.02 and 17.36 ng/g d.w.). The concentrations of S1 and S2 in soil samples were also much greater than the total concentration of other PFASs (including PFOS) that were measured. We further investigated S1 and S2 side-chain fluorinated polymer contaminants, and FOSA, FBSA and other PFASs (i.e. 13 PFCAs, 5 PFSAs and N-MeFOSA and N-EtFOSA) in biosolid samples collected in 2014 to 2017 from 20 WWTPs serving urban centres across Canada. S1 and S2 were found in the biosolid samples. PFAS concentrations in biosolid samples were also a function of treatment type, including digestion (aerobic or mesophilic anaerobic), dewatering, alkaline stabilization and/or pelletization. These findings raise a concern regarding the use of biosolids to enrich agricultural soils, which appears to be a major source vector for Ontario soil contamination with these new PFAS contaminants, and may be a human and/or terrestrial wildlife exposure issue crops grown in these biosolid-augmented fields.

**93 Assessing spatial trends and depth profiles of PFAS-contaminated soils from an AFFF-impacted site**

*A. Nickerson, Colorado School of Mines / Civil and Environmental Engineering; A. Robel, Oregon State University / Environmental and Molecular Toxicology; K. Oetjen, Sciex / Department of Environmental and Molecular Toxicology; C.P. Higgins, Colorado School of Mines / Department of Civil and Environmental Engineering; J. Field, Oregon State University / Environmental and Molecular Toxicology; J. Kornuc, US Navy*

Soil cores from a former fire training area were analyzed for a wide variety of poly- and perfluoroalkyl substances (PFASs) using liquid chromatography-quadrupole time of flight high resolution mass spectrometry (LC-QTOF-HRMS). A novel extraction method was used to enhance extraction of cationic and zwitterionic PFAS from soils, as previous methodology was insufficient for complete extraction of strongly sorbing species. The novel extraction procedure consisted of two rounds of 0.1 M ammonium hydroxide in methanol, followed by two rounds of 0.5 M hydrochloric acid in methanol. Extracts were analyzed by LC-QTOF-HRMS, with targeted quantification of 40 PFAS compounds, and spectral library and accurate mass screening against a custom-built PFAS mass spectral library and exact mass list. Identified compounds lacking analytical standards were semi-quantified and assigned different levels of confidence based on their exact mass, isotope ratios, and fragmentation. Further, the data were screened by a nontarget R script to identify any additional PFASs. Spatial concentration trends and depth profiles were examined for detected compounds. Better extraction of all PFASs more accurately captures the total environmental concentrations and improves understanding of the variable transport properties of diverse compound classes.

**94 PFAS detection at AFFF impacted sites using a fiber passive sampler**

*J. Becanova, R. Lohmann, University of Rhode Island / Graduate School of Oceanography*

Since 1950s, poly- and perfluoroalkyl substances (PFAS) have been produced for many industrial and consumer applications including aqueous film-forming foams (AFFF). Their unique chemical properties and exceptional resistance to physical-chemical and biological degradation in combination with their high production volumes led to their ubiquitous presence in the environment. In past decades, their frequent releases to the environment have caused substantial background exposure to PFASs that affect all people in U.S. As indicated by recently published data, 6 million people in the U.S. may have been exposed via drinking water to PFAS levels exceeding the water health advisories levels. Presumably, the widespread contamination of drinking water is associated with AFFF application and chemical releases from more than 600 PFAS contaminated sites around the U.S. To prevent the future PFAS exposure, an essential step, followed by subsequent corrective action (e.g. remedial projects), is to establish a quick, reliable and robust monitoring tool for the detection of PFAS at potentially contaminated sites. The use of passive samplers, which has become a routine application for hydrophobic organic contaminants is convenient for the purpose of determining dissolved PFAS concentrations in porewater. Moreover, the passive samplers provide time-weighted average concentrations in water and porewater, which can be used to assess bioavailability of PFASs at contaminated sites. Solid-phase microextraction (SPME) fibers have been successfully used previously to quantify freely dissolved concentrations of nonionic, anionic, and cationic surfactants. In this work, polyacrylate (PA) fibers were used to determine the equilibrium partitioning constant, $K_{PA\text{-}W}$ (the ratio of PFAS concentrations in solution and on the fiber at equilibrium). SPME fibers (with various PA coating) were exposed to dissolved PFASs in aqueous solution and the distribution coefficient was calculated. The log $K_{PA\_W}$ increases with increasing molar weight/ length of the carbon chain of carboxylic acids and sulfonates. Moreover, the log $K_{PA\text{-}W}$ for perfluoroamine with eight carbons in a chain was calculated and indicating strong affinity for the SPME fibers (two to three times higher in comparison with sulfonate and acid of the same carbon chain length). The calculated log $K_{PA\_W}$ for the polyfluoroosulfonates (FTS) showing a lower affinity to the SPME fiber in comparison with perfluorinated analogs.

**95 Legacy and emerging poly- and perfluoroalkyl substances (PFASs) in seabirds from Atlantic offshore and coastal environments**

*A. Robuck, Graduate School of Oceanography / University of Rhode Island / Chemical Oceanography; M.G. Cantwell, US Environmental Protection Agency; C. Gardiner, R. Lohmann, Graduate School of Oceanography / University of Rhode Island*

Poly- and perfluoroalkyl substances (PFASs) have been produced since the 1940s for use in commercial and industrial applications, including water repellant coatings, surfactants, and vinyl polymerization. PFASs demonstrate remarkable environmental persistence and bioaccumulative capacity, and have been found globally in drinking water, surface water, and biota, including birds from diverse habitats. Seabirds are particularly useful as indicators of marine ecosystem health and contamination, as their upper trophic level position allows them to assimilate resources and related biological, physical, and chemical conditions across multiple ecosystems and temporal scales. Here, PFASs were measured in juvenile birds from the Atlantic seaboard. Bird liver samples were obtained from deceased or bycatch juvenile or sub-adult herring gulls, great shearwaters, terns, and pelicans from Narragansett Bay in Rhode

Island, Massachusetts Bay off the coast of Massachusetts, and the Cape Fear River Estuary in southeastern North Carolina. Liver samples from each bird were freeze-dried and extracted using sonication, centrifugation and freezing, and purified using reversed phase solid phase extraction. Extracts were analyzed for 25 legacy and emerging ionic and neutral PFASs using liquid chromatography/tandem quadrupole mass spectrometry in electrospray ionization (ESI-) mode. Coastal birds generally contained higher concentrations of sum PFASs compared to offshore birds, with the coastal group evidencing mean concentrations of sum PFASs of 999.8 ±627 ng/g dry weight, while offshore birds displayed sum PFASs of 598.7 ±437.4 ng/g dry weight liver. PFCAs dominated the offshore group, while coastal birds contained a higher proportion of PFSAs. Concentration differences and variability in compound dominance between groups could not be attributed to trophic level as approximated by nitrogen stable isotopes, suggesting dissimilar sources may variably contribute to PFASs fingerprints observed between groups. Observed concentrations suggest abundant PFASs in seabirds from both developed coastal and remote pelagic Atlantic systems, contributed by as-of-yet uncertain pathways.

**96 Per and Polyfluoroalkyl Substances Under CERCLA**

*L. Libelo, USEPA / OLEM OSRTI SPB; S.D. Foster, K. Raffaele, USEPA / OLEM; L. Gaines, USEPA / OLEM OSRTI SPB*

Because of their long history and widespread use, per- and polyfluoroalkyl substances (PFAS) are ubiquitous contaminants in environmental media. Historical waste disposal practices, environmental release during use, and spills have led to PFAS concentrations in sites that may fall under Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), commonly known as "Superfund", authority. While PFAS are not currently listed as hazardous substances under CERCLA, analysis of soil, water, and other media at current and potential Superfund sites is increasingly identifying PFAS as potential contaminants of concern. PFAS have been detected at more than 100 sites on the National Priorities List. Many, perhaps hundreds, of additional sites may be contaminated with these chemicals, and may be eligible for remediation under CERCLA authority. Current tools for dealing with fluorochemicals at "Superfund" sites are limited. EPA is taking a number of actions to help address this situation, including: setting groundwater screening and clean-up goals for PFOA and PFOS; evaluating designation of some PFAS as hazardous substances to clarify listing and cleanup decisions and facilitate cost recovery; developing and validating analytical methods and sampling methods for quantification in different environmental media; collecting information on the number, locations and characteristics of PFAS contaminated sites; and evaluating cleanup technologies and approaches. This presentation will give an overview of EPA's activities related to PFAS under Superfund including current and ongoing efforts at characterization, potential regulation, and cleanup. The views expressed are those of the authors and do not necessarily represent the views or policies of the U.S. Environmental Protection Agency.

## Approaches and Challenges in Sediment Toxicity Testing for Environmental Risk Assessment

**97 Evaluating risk of plant protection products to benthic invertebrates: Is there harmonization of protection goals in lieu of harmonized guidance?**

*M.J. Bradley, Smithers Viscient / Ecotoxicology*

Globally, there is a general understanding that certain chemicals in the environment pose a greater threat to benthic dwelling organisms than others, generally related to inherent physical properties of the chemical. Beyond this, however, there is little agreement in the regulations as to how risk should be assessed. From determining what chemicals pose a risk, to what species should be evaluated and how these exposures should be evaluated, various regulations all take their own course. These differences are all very well outlined in the European Food Safety Authority (EFSA) 2015 Scientific Opinion on the Effect Assessment for Pesticides on Sediment Organisms in Edge-of-Field Surface Water. But what is the end result? When considering testing requirements and applied safety factors, is there a continental difference in the ultimate protection of sediment dwelling organisms? In Europe, a single long-term chironomid exposure may satisfy testing requirements, while multiple species and exposure types may be required in the United States, all with the same goal of establishing a threshold concentration protective of invertebrate benthic populations. Variable species sensitivity as well as exposure system dynamics will undoubtedly effect individual outcomes, but there is enough commonality among these designs that a similar level of protection may also be the likely outcome. Further, any differences may become moot once relative assessment factors are applied to establish risk. This presentation seeks to evaluate the relative sensitivity of standard European and USEPA test species and their respective test designs for a number of pesticide groups. These data will further be evaluated in the context of their regulatory applications and relevant safety factors to assess if largely different levels of protection exist depending on the governing body.

**98 Spatio-temporal exposure of Plant Protection Products in OECD 219 sediment test systems – Comparison of model results with measurements**

*M. McCoole, Bayer CropScience / Environmental Toxicology and Risk Assessment; K. Hammel, Bayer AG, Crop Science Division / Environmental Safety; A. Dorn, Hochschule Niederrhein / Department of Chemistry; P. Dalkmann, Bayer AG Crop Science Division; E. Bruns, Bayer AG, Division Bayer CropScience / Ecotoxicology; D. Faber, Bayer AG, Crop Science Division / BCS D ETX Ecotoxicology*

Sediment toxicity testing is currently revised under the premise to improve quality and consistency of regulatory environmental risk assessments. In 2015, the European Food Safety Authority (EFSA) published a scientific opinion on environmental risk assessment for sediment organisms where a water-spiked test system (OECD 219) is considered to study chronic effects on sediment organisms. Prominent test organisms are Chironomids, aquatic insects which live in and on soft sediments. Due to the design of this study, initially large gradients between the exposure in the overlying water and in the sediment layer are established. As a consequence, substantial temporal and spatial dynamics of local concentrations have to be expected, especially in the vicinity of the interface beween water and sediment where the Chironomids inhabit. To describe local concentrations in such water-sediment test systems, we simulated the transport and the redistribution of two moderately mobile ($K_{OC}$ 200 to 300 L/kg) plant protection products with the mechanistic model TOXSWA. The results of the simulation are compared with measured sediment concentrations in three depths (see poster submitted by McCoole et al. in this session). The compound properties were parameterised using values derived independently in standard tests ($K_{OC}$, $DT50_{water/sediement}$) or from literature (diffusion coefficients). Other parameters were derived from OECD 219 experimental design information. The simulations matched the measured concentrations spatially and temporally well. The simulated concentration depth profiles averaged for the layers which were measured lay almost always within the range of single measurements. Also the concentrations in the overlying water were reproduced well. The main findings are that the concentrations in the sediment show a pronounced temporal pattern and that the concentrations in the sediment are strongly depth-dependent. The dominant transport process in the sediment is obviously diffusion which, however, did not lead to homogeneous penetration of the sediment. Presuming that Chironomids live in the upper three millimetres of the sediment, they are exposed to approximately four times higher test compound concentration (total and liquid) than the average concentration in the sediment. This has important consequences for the derivation of effect endpoints of Chironomids from OECD 219 study data, which should consider the local exposure of the organisms.

**99 Influences of Environmental and Anthropegenic Contaminants on Bacterial Communities in Sediments of the West Coast of Korea**

*J. Lee, Seoul National University; S. Hong, Chungnam National University / Department of Ocean Environmental Sciences; B. Kwon, Seoul National University / School of Earth and Environmental Sciences; J. Ryu, Anyang University / Department of Marine Biotechnology; X. Zhang, Nanjing University / Environmental Science; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences and Toxicology Centre; J. Khim, Seoul National University / School of Earth and Environmental Sciences*

Bacterial communities in coastal sediments are recognized to play a significant role in the ocean ecosystem functioning and regulate relevant biogeochemical processes. Chemical contaminants, such as heavy metals, polycyclic aromatic hydrocarbons (PAHs), and alkylphenols (APs) can accumulate in sediments and (in)directly influence corresponding bacterial communities. Nevertheless, relatively few studies have investigated the link of bacterial community diversity to anthropogenic stresses, particularly in long-term aspect. In the present study, we aimed to 1) investigate spatiotemporal changes of the bacterial communities in sediments collected from the west coast of Korea, particularly including the severely polluted coastal sites along the coast, from 2010 to 2014, 2) assess the relationship between sediment bacterial communities (viz., bacterial diversity and community composition) and sedimentary pollutants, such as PAHs, APs, and heavy metals, and 3) identify the potential toxicities of AhR- and ER-active chemicals present in sediment samples. The diversity of bacterial communities was not significantly correlated with salinity, AhR-, ER-mediated activities, and concentrations of APs, whilst heavy metals and PAHs seemed to strongly influence on the structure of bacterial communities. In specific, the community of phylum Planctomycetes showed significantly negative correlations to concentrations of heavy metals and PAHs. Overall, the results suggested that the sediment bacterial community could be one potential proxy component to address the pollution status in the integrated sediment assessment.

**100 Application of different extraction methods in screening for the effects of a tropical freshwater dam sediment on the steroidogenesis of H295R cells**

*A. Adeogun, University of Ibadan, Nigeria / Zoology; L. Natoli, G. Luci, A. Arukwe, Norwegian Univewrsity of Science and Technology (NTNU) / Department of Biology*

In the present study H295R human cells were used to investigate the endocrine disruptor potential of three different sediment extracts taken from a Nigerian freshwater dam (Awba Dam). Each extract (polar compounds extract, non-polar compounds extract and elutriate) permits to selectively take into consideration different group of contaminants in relation to their binding affinity with sediments particles (mainly driven by polarity), and by consequence assessing the relevance of different exposure routes that each contaminant is more likely to undergo (resuspension, direct ingestion and trophic web transfer or diffusion at the water sediment interface). After exposure to different concentration of each extract, H295R cells were evaluated with regards to expression profiles for 10 genes heavily involved in steroidogenesis (*cyp11a, cyp11b2, cyp17, cyp19, cyp21, 3β-hsd2, 17β-hsd1, 17β-hsd4, star, hmgr*) and for the synthesis of estradiol and testosterone. Our results showed similar increased expression, going from the lower to the highest concentration for *17βhsd1, 3βhsd2* and *cyp21* in the cells treated with the polar and non-polar extracts. *star*, *hmgr*, *cyp11b2* and *17β-hsd4* were slightly down regulated in the polar treatment and up regulated in the non-polar extracts treatment especially in the highest concentration. The *cyp11a* and *cyp17* showed completely opposite behavior in the polar and non-polar extract treatments. Estradiol levels were significantly higher in the cell treated with the non-polar extracts at all concentrations. Elutriate exposure led to less pronounced variations with regard to both mRNA levels and hormone synthesis. Overall the extract with non-polar compounds induced the most dramatic variation in H295R cells and by consequence, most probably, the direct ingestion of detritus and mud from fishes and other benthonic organisms in the area, and consequent possible transfer throughout the trophic web, is mainly accountable for the alteration of the endocrine system previously observed for fish such as Tilapia species in the study site.

**101 Effects of sediments spiked with low fluoranthene concentrations on juvenile prawns from Tecolulta, Veracruz, Mexico**

*P. Ramirez Romero, M. del Carmen Guzman Martinez, E. Hernandez-Elizalde, L. Elizalde-Ramirez, Universidad Autonoma Metropolitana Iztapalapa / Hydrobiology*

Polycyclic aromatic hydrocarbons (PAH) are common pollutants in aquatic environments because of their hydrophobic nature, they are deposited in sediments where they can be persistent. Fluoranthene (Fl) is considered a model PAH; it is genotoxic, carcinogenic, mutagenic and teratogenic; so exposure to this compound can represent a serious environmental risk. The aim of this work was to evaluate the effects of sediments contaminated with low fluoranthene concentrations (> EPA SQC) on juvenile prawns of the genus *Macrobrachium*. Sediments and organisms were collected in the Tecolutla estuary (Veracruz, Mexico) and transported to Mexico City in 20 L container. While the prawns acclimated for a month to laboratory conditions, sediments were dried, sieved and spiked to prepare a control and two concentrations: 225 and 450 µgFl/gOC. A 21day bioassay was carried out, with 25 organisms (average length 5 cm; 1 g of wet weight ) per concentration. During the bioassay, the following parameters were monitored and evaluated: oxygen:nitrogen ratio (O:N), lysosomal stability and swimming resistance, these evaluations were carried out on days 7, 11, 18 and 21. Swimming resistance decreased as time passed, the control group showed the highest values (average 50 sec), followed by prawns exposed to 225 µgFl/gOC and finally those in 450 µgFl/gOC (14 sec on day 21). The same pattern was observed in the O:N ratio (with average O:N of 98, 28 y 21 respectively) and the retention time in the lysosomal stability test (180 min, 120 min and 60 min respectively on day 21). In conclusion fluoranthene concentrations below the EPA SQC did not cause mortality but the physiological effects observed in juvenile prawns indicated that they are stressed and at a higher risk of being predated, which could lower their survival chances.

**102 State of the Science of Mayfly Ecotoxicity Testing**

*J.R. Wirtz, Compliance Services International; M. McCoole, Bayer CropScience / Environmental Toxicology and Risk Assessment; P.K. Sibley, University of Guelph / School of Environmental Sciences; L.L. Lagadic, Bayer Ag / Environmental Safety; D.J. Soucek, Illinois Natural History Survey; T.J. Norberg-King, USEPA / NHEERL / Mid-Continent Ecology Division; I. Roessink, Alterra / Environmental Risk Assessment*

The historical choice of invertebrate species used in most current water and sediment toxicity test protocols represents a combination of practical (*e.g.*, amenity to year-round laboratory culturing, ease of maintenance, and regulatory acceptability) and ecological (*e.g.*, geographic and habitat representation, feeding habits, and relative sensitivity) considerations. This has led to the development of widely applied toxicity test protocols that incorporate reliable, though not necessarily highly sensitive test species. Early exploration of candidate species for toxicity testing included evaluation of EPT (Ephemeroptera, Plecoptera, Trichoptera) taxa. However, many of these were found to be difficult to culture (*e.g.*, many EPT taxa require flowing water), biological requirements were not well known, most would not reproduce under laboratory conditions, and many were sensitive to the laboratory environment (often failing to meet control test acceptability criteria during tests). Such early efforts with EPT species were therefore largely abandoned in favor of more pragmatic species (e.g., *Daphnia magna*, *Ceriodaphnia dubia*, *Hyalella azteca*, *Chironomus dilutus*/*riparius*) now used in most of the standard toxicity test protocols. However, field and laboratory studies have consistently shown that the EPT group of insects contain some of the most sensitive species to environmental contaminants. In recognition of recent advances in culturing and application in aqueous and sediment-based toxicity testing of EPT species, a project was initiated to report on the state of the science for the application of mayflies in ecotoxicity testing. The first part of the project involved a literature search for peer-reviewed and grey literature on Ephemeroptera species that covers their ecology, species' ranges, relative sensitivity among mayfly species used in toxicity tests, and a comparison of the sensitivity of mayflies to standard aquatic toxicity test species. Key goals of the project include the identification and prioritization of knowledge gaps that can serve as areas for future research, the assessment of the prospect for routine incorporation of mayflies in toxicity testing, and the creation of standardized toxicity test protocols. *Disclaimer: This presentation does not necessarily reflect the views or the policies of the U.S. Environmental Protection Agency.*

**103 Evaluating the Relative Sensitivity of the "P&T" in EPT: Implications for Standardized Toxicity Testing**

*P.K. Sibley, M. Raby, University of Guelph / School of Environmental Sciences; J.R. Wirtz, Compliance Services International; M. McCoole, Bayer CropScience / Environmental Toxicology and Risk Assessment; L.L. Lagadic, Bayer Ag / Environmental Safety; D.J. Soucek, Illinois Natural History Survey; T.J. Norberg-King, USEPA / NHEERL / Mid-Continent Ecology Division; I. Roessink, Alterra / Environmental Risk Assessment*

The EPT (Ephemeroptera, Plecoptera, and Trichoptera) group of insects are widely applied as indicators of water quality in biomonitoring because they contain some of the most sensitive species to environmental pollutants. This widespread application in the field has not translated into standardized lab-based toxicity tests, in part, because many of the taxa tested in the early days of test development were difficult to culture due to unique environmental requirements (e.g., flowing water), most would not reproduce under laboratory conditions, and some were sensitive to the lab environment (often failing to meet control test acceptability criteria). In the past few years, however, interest in developing standard toxicity test protocols using EPT taxa has been renewed due to improved methods for culturing, development of novel exposure systems for obligate flowing water species, and an improved understanding of biological requirements. To date, much of this effort has focused on European and North American species of Ephemeroptera (mayflies) but recent testing with both Plecoptera (stoneflies) and Trichoptera (caddisflies) with neonicotinoid insecticides indicates that standardized exposure protocols may be possible. In this presentation, we will review historical and recent applications of Plecoptera and Trichoptera species in toxicity testing with the goal of evaluating their suitability for lab-based chemical assessments. In addition to practical considerations, we examined the relative sensitivity of EPT taxa based on studies derived from the literature and the application of Species Sensitivity Distributions developed for hazard assessments with neonicotinoid insecticides. We show that Ephemeropteran species, on average, are more sensitive than Plecopteran and Trichopteran species but that there is wide variation within and between the orders depending on genus, life history characteristics, and chemical class.

**104 Improving Sediment Toxicity Test Interpretation at Mega Sites Using Novel Approaches to Batch Normalization**

*S.A. Roark, Jacobs / Environmental & Nuclear; K. O'Neal, Jacobs / Global Environmental Services; F.S. Dillon, CH2M Hill / Global Environmental Services; D. Mount, USEPA / ORD / NHEERL / Mid-Continent Ecology Division-Duluth, MN*

Sediment toxicity tests are an important tool used in ecological risk assessments for contaminated sediment sites, but interpreting test results and defining toxicity is often a challenge. This is particularly true at mega-sites where a large testing regime necessitates performing bioassays in a sequence of batches, each evaluating a subset of the samples. Batched testing introduces variability and uncertainty that add to the challenge of interpreting results. Accounting for variability introduced by batched data collection is important. The absolute performance of test organisms is influenced by multiple factors, which contributes to variation among batches of sediment toxicity tests. These factors include the starting size, age, and health of the organisms used, conditions within each test, and random variation. For analyses that incorporate data from multiple batches of sediment exposures, the presumed goal is to parse differences in organism performance between batch-related variation and contamination-induced changes, such that the overall exposure-response gradient can be evaluated independent of batch-related variation. Variation among batches is often addressed by normalizing test sample results to control sample results, but this approach has potential for creating artifacts in the analysis. Alternative approaches include, for example, normalizing the results in each batch to a fixed percentile of the response distribution of each batch, and normalizing test results to the median (or other statistic) response in each batch associated with reference samples or with site samples determined sufficiently uncontaminated that no substantive biological response is expected. We used simulated bioassay data sets generated by resampling from log-logistic concentration response models (based on the results from real bioassays), to compare results among normalization procedures. The advantage of using simulated data was that we could separately evaluate the effectiveness of normalization approaches under specific batch variation scenarios (e.g., reduced control performance relative to test samples in some batches). The results of the simulation study illustrate the unintended results that can occur with control normalization, and the potential advantages of alternative approaches. However, there are assumptions implicit to each approach, and the most suitable approach may depend on specific characteristics of the bioassay data set.

## Wildlife Ecotoxicology Supporting Management Decision Making

**105 Characterizing risks to wildlife: Proposals for improving laboratory protocols and integration of alternative lines of evidence**

*M.S. Johnson, US Army Public Health Center / Toxicology; B.E. Sample, Ecological Risk, Inc.*

Predicting risk to wildlife species from exposures to chemicals requires an understanding of class-specific toxicology and variation of sensitivity within a class. Few laboratory wildlife models exist and there are few examples of controlled laboratory study designs that support toxicity reference value derivation. Incomplete toxicity data sets, variation in response, differences in study conduct, and statistical error all contribute to variations in interpretation. For example, differences between species might be due to variation in toxicokinetics driven by environmentally weathered forms, differences in gastrointestinal physiologies, or differences in exposure characteristics. Toxicodynamic differences within a vertebrate class also have the potential to affect toxicologic sensitivity and affects the predictive capabilities of risk assessments. Here we present some of the challenges and sources for variation in predictive toxicity benchmarks and provide some solutions for higher tiered post hoc risk assessments. In addition, some suggestions for toxicology protocol development are also presented to help improve predictive utility of toxicity-based benchmarks.

**106 What Do Tissue Residues Tell Us About the Utility of Body Weight Scaling for Interspecies Extrapolations in Wildlife?**

*P.C. Fuchsman, L. Brown, A. O'Connor, M.H. Henning, Ramboll*

Differences among bird or mammal species' responses to contaminant exposures reflect differences in toxicokinetics (where chemicals go after being taken into the body) and toxicodynamics (how chemicals interact with the site of toxic action). An important factor affecting interspecies toxicokinetic differences is metabolic rate, which is a function of body weight. Bioaccumulation takes longer to reach equilibrium in larger animals, and equilibrium concentrations in tissues are higher, due to slower metabolism compared to small animals. During the 1990s, ecological risk assessors used a body weight scaling approach to account for this phenomenon, for purposes of extrapolating toxicity data among species with different body weights. Efforts were made at that time to determine chemical-specific scaling factors through comparisons of acute toxicity test results among species, but this effort produced implausible results, likely because the internal exposures of larger species had not reached equilibrium during the acute tests. In 2007, a group of leading wildlife risk assessors concluded that in the absence of sufficient multispecies chronic toxicity data sets, body weight scaling should be dropped from ecological risk assessment practice. On the other hand, in 2011, the U.S. Environmental Protection Agency extended the use of body weight scaling in human health risk assessment, for purposes of determining reference doses from animal test results. We suggest that multispecies data sets from chronic bioaccumulation studies provide a potentially useful line of evidence to address the current lack of coherence in interspecies extrapolation practices. As case studies, we examine extensive laboratory and field data for avian bioaccumulation of cadmium, mercury, and PCBs. We compare how well different measures of exposure account for interspecies variation in the relationship between external and internal contaminant exposures. Exposure metrics include dietary concentrations, doses (as mg chemical per kg body weight per day), and mallard-equivalent doses (determined by body weight scaling). Our findings suggest it may be time to rethink the current practice of extrapolating toxicity data among species on a dose basis without accounting for differences in body weight.

**107 Field Studies to Support Management of Molybdenum Exposure to Mule Deer and Elk at a Molybdenum Mine in New Mexico**

*B.E. Sample, Ecological Risk, Inc.; C. Lambert, Intrinsik Environmental Sciences US, Inc.; A. Thomason, Intrinsik Environment Sciences, Inc.; C. Meyer, ARCADIS; M. Batchelder, Arcadis US, Inc.; C.L. Murray-Gulde, Chevron Environmental Management Co.*

Molybdenum (Mo) mine tailings from a mine in New Mexico were deposited in the Tailing Facility (TF). Closure of the TF requires the replacement of the current variable soil cover and establishment of a native plant community. Mule deer and elk that currently forage on the TF may be exposed to Mo in tailings through plant bioaccumulation. To minimize potential exposure, plants selected for the future final cover should minimize both Mo bioaccumulation and preference as forage for deer and elk. Diet composition of deer and elk currently grazing on the TF was determined over four seasons using plant chloroplast DNA identified in scat samples and quantified by comparing scat DNA to the site-specific DNA reference library and to a more comprehensive DNA database from the European Molecular Biology Laboratory. Bioaccumulation was described using both loglinear regression and bioaccumulation factors (BAF) for co-located soil and foliage samples for 17 plant species (14 in and 3 not in diets). Although plant species consumed overlap, diets of elk and deer vary relative to each other and seasonally. Diet data strongly indicate substantial portions of diets are obtained off-site. Most common species growing on TF in the diet of both species were prickly lettuce, yellow sweet clover, alfalfa, hairy false goldenaster , common sunflower , hoary tansyaster, ragleaf bahia, and big sagebrush. Mo bioaccumulation rates vary by plant species. Both elk and deer at the TF displayed higher preferences for plant species that accumulated greater Mo. The 4 species that accumulated the greatest Mo (yellow sweetclover, alfalfa, ragleaf bahia, and hairy goldaster) were ranked 1, 2, 3, and 5 and 1, 2, 3, and 4 in diet preference for elk and deer, respectively. Mean Cu:Mo ratios were below PNEC of 1.3 for all 17 plant species evaluated, suggesting potential for toxicity. Of 6 plants with the lowest Cu:Mo ratios, only western wheatgrass was not consumed by elk or deer. The remaining 5 species, ordered by increasing Cu:Mo ratios, are Indian ricegrass, smooth brome, yellow sweetclover, alfalfa, and needle and thread grass. Based on these results, 6 species (rubber rabbitbrush, blue grama, bottlebrush squirreltail, big sagebrush, western wheatgrass, and common sunflower) should be considered for re-vegetation seeding mix. Alfalfa and yellow sweetclover, should be excluded due to their forage preference, high molybdenum bioaccumulation rates and low Cu:Mo ratios.

**108 Should ERAs Include Mammals? Tales from a Gray Fox Study**

*L.V. Tannenbaum, D. Bullis, Army Public Health Center; N. Deuel, University of Georgia; M. Conner, Joseph W. Jones Ecological Research Center; M. Chamberlain, K. Miller, University of Georgia*

Ecological risk assessments (ERAs) should only evaluate those species that are spatially relevant to their contaminated environs. To that end, ERA practitioners should seek out opportunities to establish that species they may believe to be of interest, actually satisfy a key, but often overlooked receptor-of-concern selection criterion, namely a demonstrated high site fidelity. The use of newly available, state-of-the-art GPS tracking equipment to investigate the worthiness of gray fox (*Urocyon cinereoargenteus*) inclusion in terrestrial assessments, brings forward exposure information of great value. As with the outcome of a similar spatial movements tracking effort for White-tailed deer (presented at a SETAC N.A. meeting a number of years ago), gray fox will probably never be appropriate for consideration within an ERA setting. The high-quality actual, as opposed to modeled, exposure data of this study constitutes a classical example for wildlife ecotoxicology information supporting management decision-making. The specific data presented contributes to a growing and persuasive argument that mammal inclusion in ERAs for Superfund-type sites is quite unnecessary.

**109 The Use of Geographic Information Systems (GIS) for Spatial Ecological Risk Assessments: An example from the Athabasca Oil Sands area in Canada**

*K. Eccles, University of Ottawa / Department of Biology; B. Pauli, Environment and Climate Change Canada / National Wildlife Research Centre; L. Chan, University of Ottawa / Biology*

Modelling impacts of chemical mixture exposures across a landscape is challenging due to the spatial heterogeneity and complexity of the sources, pathways, and fate of the multiple chemicals in the mixture. This is especially true for estimating exposure of wildlife living in areas of intense anthropogenic disturbance such as the Athabasca Oil Sands area in Canada. In the field of ecotoxicology there is an acknowledged need to include spatial analyses to develop more accurate risk assessment. As a result, the field of landscape ecotoxicology emerged, which studies the spatial distribution of contaminants across a landscape and the impact on ecological systems. While landscape ecotoxicology and spatial analyses can theoretically be useful for risk assessment purposes, they have yet to become common practice due to the underdevelopment or standardization of methodology. Here, we propose and demonstrate the use of geographic information systems (GIS) as a tool to integrate data, assess large spatial scale patterns across contaminants and species, and assess complex exposures for landscape ecotoxicological assessment using data collected under the Joint Oil Sands Monitoring (JOSM) project in the Athabasca Oil Sands area. This dataset is comprised of 1100 biological samples from five individual biomonitoring projects on tree swallows, amphibians, gull and tern eggs, plants, and terrestrial and semi-aquatic mammals. The samples were analyzed for a variety of contaminants including metals and polycyclic aromatic compounds (PACs), and biological health endpoints. The data were spatially combined and mathematically integrated in ArcGIS 10.4 and analyzed using spatial methods such as Getis-Ord's Gi*, Moran's I, and spatial densities to assess landscape level spatial patterns. The results and spatial patterns are intuitively communicated through maps. Our results demonstrate that GIS models can be used in spatial ecological risk assessment and in developing evidence-based long-term ecological monitoring programs.

**110 Population Viability Management to Inform California Condor Conservation**

*M. Finkelstein, University of California Santa Cruz / Microbiology and Environmental Toxicology; V.J. Bakker, Montana State University / Department of Ecology; D.F. Doak, University of Colorado at Boulder / Environmental Studies; S. Kirkland, US Fish and Wildlife Service / Hopper Mountain National Wildlife Refuge Complex; J. Brandt, US Fish and Wildlife Service; R. Wolstenholme, National Park Service; J. Burnett, Ventana Wildlife Society; D.R. Smith, University of California Santa Cruz / Microbiology and Environmental Toxicology*

Population variability analysis (PVA) has long been recognized as a valuable tool to assess population status and trends in wild species. However, the integration of toxicology data into PVA models is still relatively rare. Population viability management (PVM) models incorporate management into the PVA structure in order to predict the effects of alternative management actions on population stability and growth. We stable lead as well as carbon and nitrogen isotopic analyses to demonstrate that ingestion of spent lead ammunition from feeding on carcasses was the principal source of lead to free-flying California condors (*Gymnogyps californianus*) in California and that condors were exposed to DDE from feeding on marine mammals. We then constructed a PVM for condors to quantify the effects of contaminant exposure (e.g., lead, DDE) and multiple management actions on population growth. We found that lead poisoning is the primary threat preventing condor recovery in the wild. Our published results of this work informed legislation, leading the California legislature to pass and Governor Brown to sign into law in 2013 a ban on lead-based ammunition for hunting within the state of California that will be fully implemented by 2019. Currently, we are using PVM to prioritize management actions for the effective use of limited management resources to enhance condor population growth under different conditions, such as mortality from lead poisoning and reduced reproduction from DDE. Adult condor survival is the most important factor for population growth and lead is the main threat affecting adult survival. Consistent with this, our analyses found that nest management, which increases chick survival, is less important to long-term (e.g., 30-year) population growth than releasing captive-bred condors. We have also shown that establishing a new condor release site, which will reduce the number of available captive-bred condors for release to existing flocks, decreases the population growth rate of condors in California, though this effect can be mitigated by increasing the number of captive-bred birds available for release into the wild. Our findings demonstrate how toxicology data and management practices can be used in a PVM framework to provide important quantitative predictions on population health to inform policy and management.

**111 Challenges in Monitoring Anticoagulant Rodenticides in Wildlife in California**

*S. McMillin, CA Dept of Fish and Wildlife*

The California Department of Fish and Wildlife (CDFW) has been monitoring anticoagulant rodenticide exposure in wildlife since the 1990s. These findings were used by the California Department of Pesticide Regulation to designate second-generation anticoagulant rodenticides California restricted use materials in 2014. CDFW has continued this monitoring project to evaluate effectiveness of the regulation change. Interpretation of these data is challenging for a number of reasons. First, inherent biases in sample collection are difficult to avoid. For example, most of the carcasses submitted for analysis are collected by wildlife rehabilitation centers, usually located near populous areas of the state. However, some studies have taken advantage of opportunities for less biased sampling, such as the statewide mountain lion study, the Bakersfield San Joaquin kit fox study, and the fisher study. Second, careful interpretation of both pesticide residue and clinical findings is required. Differences in species sensitivity to anticoagulants and in toxic effects of different active ingredients, as well as changing reporting limits, may complicate interpretation of quantitative findings. Also, co-occurring mortality factors such as trauma and disease, must be considered when making conclusions from necropsy findings. Finally, exposure circumstances can be difficult to determine. Many predators and scavengers have large ranges so locations of exposure are unknown. Additionally, for most submissions it is impossible to determine if clinical toxicity cases resulted from a single exposure event or multiple exposures. Information about dietary sources of exposure is lacking, especially for species with diverse diets. While these factors must be considered when attempting to describe effects of anticoagulant rodenticides on wildlife, some conclusions can be made from the data, including continued exposure of a wide range of wildlife species distributed throughout the state three years after regulation change and continued cases of intoxication from these exposures.

**112 Wildlife Ecotoxicology in California Natural Resource Damage Assessments**

*C. Marn, US FWS / San Francisco Bay-Delta Fish and Wildlife Office*

When wildlife and other natural resources are injured as a result of the release of hazardous substances or the discharge of oil into navigable waters, federal, state, and tribal governments in the United States may act on behalf of the public to seek compensation from responsible parties to restore injured resources. Natural resource trustees have the authority under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) and the Oil Pollution Act (OPA) to conduct natural resource damage assessments (NRDA) to assess injuries to natural resources and quantify monetary damages. Damages recovered are used to restore the injured resources and compensate for lost services. As defined in CERCLA and OPA, NRDA is a process to evaluate the nature and extent of injuries to natural resources and services resulting from the release/spill and to determine the restoration actions needed to recover injured resources back to the baseline conditions that would have existed had the release or spill not occurred. Natural resource trustees must determine whether injuries have resulted from the release/spill and quantify the degree, and spatial and temporal extent of the injuries relative to baseline before developing restoration alternatives. In support of the claim for restoration, natural resource trustees may use data from field studies, laboratory studies, modeling, and published literature. Examples of data collected from California NRDA cases, specifically related to assessment of injuries to wildlife and other biota will be presented to illustrate the NRDA process.

## The Need for Data and Data Management Tools to Address ESA-listed Species Protection and Agricultural Production Goals

**113 Exploring Complementary Options that Optimize the FIFRA/ESA Process**

*L. Duzy, A.R. Frank, B.D. McGaughey, Compliance Services International; T. Carro, P. Whatling, FMC Corporation*

Under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), the process of assessing the potential impact of pesticide use on species listed under the Endangered Species Act (ESA) can be resource intensive for all stakeholders. In order to address risk management and species protection, there is interest in exploring alternatives or complements to the current process. Boyd's OODA Loop is applied to the process of building options. One option is to frame and evaluate risk and uncertainty given best available data to evaluate reasonable and affordable voluntary mitigation or management options, such as targeted conservation to effectively protect and enhance listed species and their habitats while efficiently bringing new products and product uses through the registration and consultation process. This presentation will introduce the exploratory efforts underway to understand and combine use site, species, product, and economic factors in a way that builds a basis for development of strategies to achieve effective and protective registration actions.

**114 Integrating multiple sources of data to characterize the risk of contaminants to ESA-listed species; Part I – visually consolidating data**

*D.H. Baldwin, NOAA Fisheries / Northwest Fisheries Science Center; R.J. DeWitt, The Evergreen State College / Office of Protected Resources Endangered Species Division; T. Hooper, NOAA / NMFS; C.A. Laetz, NOAA / NMFS / Northwest Fisheries Science Center; S.A. Hecht, NOAA / National Marine Fisheries Service; T. Hawkes, National Marine Fisheries Service / Office of Protect Resources*

Assessing the risk posed to an ESA-listed species by contaminant exposures requires integrating numerous types of information. Much of the information will be species-specific and vary with time, space, and habitat. A given contaminant, for example, can arise from different sources and enter different habitats for varying times. Even for a single species, therefore, there can be numerous, different potential exposure concentrations each with their own uncertainty or variability. Comparing the locations of the sources of exposure to species range and life-history information is also important. Finally, numerous species-specific toxicity endpoints for the contaminant need to be considered. Examples include both lethal and sublethal effects (e.g. mortality, growth and behavior) as well as habitat-mediated effects (e.g. impacts on prey abundance). This presentation will summarize an approach to gathering the relevant data for a species into a single plot designed to help characterize the risk posed by a contaminant (an “R-Plot”). The current tool is based on R and automates the generation of a plot that displays these multiple sources of data in one figure. An example will be presented for the risk posed by a pesticide to an aquatic species.

**115 Integrating multiple sources of data to characterize the risk of contaminants to ESA-listed species; Part II-application to pesticide consultation**

*R.J. DeWitt, The Evergreen State College / Office of Protected Resources Endangered Species Division; D.H. Baldwin, NOAA Fisheries / Northwest Fisheries Science Center; T. Hooper, NOAA Fisheries / Office of Protected Resources Endangered Species Division; C.A. Laetz, NOAA /NMFS / Northwest Fisheries Science Center; S.A. Hecht, NOAA / National Marine Fisheries Service; T. Hawkes, National Marine Fisheries Service / Office of Protect Resources*

Evaluating the effects of EPA’s nationwide authorization of pesticides to federally-listed threatened and endangered species requires integrating numerous types of information including species-specific life-history information; exposure estimates that vary with time, space, and habitat type; and multiple types of effects data relevant to a species fitness including sublethal effects, lethal effects, and habitat-mediated effects. In a recent biological opinion, National Marine Fisheries Service developed an approach for gathering relevant data for a species into a single plot (an “R-Plot”). This presentation will describe how R-Plots were used to inform the effect, likelihood, and confidence of pesticide exposures to aquatic ESA-listed species. In addition, how data were selected and how R-Plots were utilized to assign low, medium and high rankings to pesticide use categories will be described. Finally, an overview will be provided on how the resulting rankings were then integrated into the overall assessment of risk to populations of federally-listed species and their designated critical habitats.

**116 FIFRA/ESA Assessments and Beyond: How FESTF’s Data Management Tool, Gopher, Answers Questions and Provides Options**

*A.R. Frank, Compliance Services International; T. Hall, Bayer / Environmental Toxicology and Risk Assessment; D. Campbell, Syngenta / Department of Regulatory Affairs; B.D. McGaughey, Compliance Services International*

The 2017 release of the US Environmental Protection Agency’s (USEPA) first Biological Evaluations (BE) under Registration Review to include national-level endangered species assessments, and subsequently the 2018 Biological Opinion (BO) from the National Marine Fisheries Service (NMFS), illustrated some of the challenges of balancing pesticide registration decisions with agricultural production and endangered species protection objectives. Specifically, the limited availability of pesticide use data, refined species distribution information, and the lack of a data management tool to aggregate and analyze such data made it difficult to adequately consider both objectives. The FIFRA Endangered Species Task Force (FESTF) has contributed to the US Environmental Protection Agency’s (USEPA) endangered species and pesticide data development process for nearly 20 years and has recently completed an enhanced service tool – Gopher – that integrates best available datasets related to pesticides and endangered species into a single tool. Using examples from the BE and the BO, this presentation will illustrate how Gopher can be used to manage, synthesize, spatially interact with, and retrieve data to bring efficiency to the process. Future enhancements of the system will be discussed including ways to better inform Environmental Baselines with incorporation of pesticide use data and capturing on-the-ground conservation efforts.

**117 My Compliance Program has a Weed Problem: Managing Aquatic Plants in the Sacramento-San Joaquin River Delta**

*J. Madsen, P. Moran, P. Pratt, USDA / ARS; E. Hard, California; J. Caudill, California State Parks / Division of Boating and Waterways; W. Pratt, Crowe Horwath; D. Bubenheim, NASA / Ames Research Center*

The Sacramento-San Joaquin River Delta (“Delta”) is the largest freshwater estuary on the West Coast, and provides critical water resources, ecosystem services, and habitat to 56 rare, threatened, or endangered species. Water resource provision and species habitats are imperiled by infestations of invasive aquatic plants, including waterhyacinth, Brazilian waterweed, and waterprimrose; which obstruct water supply, navigation, and endangered species survival. Environmental regulatory requirements affect all aspects and activities in managing these species, from planning through implementation, site selection, and setbacks. Compliance with federal Endangered Species Act has resulted in pesticide and surfactant testing for all life history stages and food chain trophic levels for Delta smelt and pacific salmonids, as well as additional oversight and setbacks for giant garter snake and valley elderberry longhorn beetle habitats. While these additions have potentially decreased risk of harm to endangered species, the cost to successfully manage the invasive plant problem has increased dramatically while reducing the available tools. Much of the floating aquatic vegetation management must either be delayed or suspended to accommodate timing and setback requirements, submersed plant treatments have to utilize repeated treatments of a more expensive alternative in lieu of a less expensive herbicide. Despite these obstacles, management of waterhyacinth in 2017 managed to keep up with growth after the explosive growth in 2014, 2015, and 2016. Intensive research and development activity has resulted in the introduction of herbicides and surfactants with lower risks to species of concern. Research by USDA ARS has led to the release of new biological control agents for waterhyacinth and giant reed. A decision support tool has been developed to provide acreage of waterhyacinth and waterprimrose estimates from LandSat data on a biweekly basis, increasing the ability to locate nursery populations of these weeds. The management of invasive aquatic plants has been recognized as a critical component to the recovery of Delta smelt populations in the Delta. An adaptive integrated pest management approach has been developed for effective management of invasive aquatic plants that fully considers the environmental impacts on endangered species and environmental compliance of with a full range of regulatory concerns.

**118 Methods for Generating Best Available Agricultural Land Use Data in Support of Pesticide Ecological Risk Assessments**

*A. Nickelson, Washington State Department of Agriculture / Directors Office; P. Beale, J. Demory, G.R. Tuttle, Washington State Department of Agriculture / Natural Resources Assessment Section*

The USEPA and partner agencies are required to assess all registered pesticide uses for their potential impacts on all species listed under the

Endangered Species Act (ESA). In the context of the risk assessment process it is imperative to identify data sets that have a high degree of accuracy in order minimize the amount of uncertainty in the risk estimates and to avoid relying on assumptions that could be excessively conservative. The importance of utilizing land use data and pesticide use data that have a high degree of accuracy is one example that cannot be overstated because they are both directly involved in estimating the risk associated with specific pesticide uses. Because mandatory pesticide use reporting data is scarce, risk assessors rely on the best available data and modeling efforts. In 2002, the Washington State Department of Agriculture (WSDA) began developing a statewide agricultural land use mapping program to generate data utilizing GIS technologies that would be able to provide highly accurate land use data for the purpose of informing pesticide's risk assessments for endangered species. Mapping programs like the one developed by WSDA are especially important because standard remote sensing technology is more problematic in areas where there are a large variety of crops like Washington State which has over 300 different crop types. The geospatial dataset is published to a geodatabase where the data is then accessible via web maps and mobile apps and can be used quantitatively by researchers and risk assessors as well as a wide range of other user groups. Staff involved with the data collection at WSDA also work closely with the United States Department of Agriculture (USDA) and participates in the Cropland Data Layer (CDL) project by providing Washington State specific ground-truthed data for their satellite product. Participation in the CDL project ensures that the data representing Washington State in the CDL is as accurate as possible and is available for use for national assessments by federal agencies.

**119 Managing pesticides and the watersheds of Washington State for the protection of ESA species, and economic vitality**

*W.G. Landis, E.J. Lawrence, Western Washington University / Institute of Environmental Toxicology; V. Chu, Western Washington University / Environmental Science; C. Mitchell, Washington State University / School of the Environment; J.D. Stark, Washington State University / Dept of Entomology; K. von Stackelberg, NEK Associates LTD / Department of Environmental Health*

The watersheds of Washington State are managed by multiple state, federal and tribal agencies to ensure multiple ecosystem services. Agricultural productivity in the Skagit, Nooksack and Yakima watersheds are vital to the economy of the state. Chinook salmon are an iconic species of the Northwest and the evolutionary significant units are protected by the Endangered Species Act. The runs of Chinook Salmon are also of cultural importance to the Tribes and to many of the cultural groups in the region. The salmon runs are also economic events. The Skagit Eagle Festival in Concrete, WA and along the watershed in the winter is a major tourist event with thousands of Bald Eagles drawn by the runs of the Chinook salmon. In the Yakima River dams are present to supply irrigation and pesticides are applied to assure the agricultural productivity of the region. However, the dams are barriers to passage for Chinook passage, isolating some salmon populations. Pesticides are toxic to the fish and to the necessary invertebrate assemblages. Across the State global climate change is altering water temperature, the type of precipitation during winter, the timing of flood events and ocean acidification is lowering the pH of near shore marine waters. A quantitative framework is required to evaluate the effects of multiple stressors on the multiple ecosystem services provided by the vital watersheds across the Puget Sound and Columbia watersheds. Bayesian network risk assessments have been built to describe the interactions of organophosphate pesticides, in-stream dissolved oxygen and temperature, land use, changes in pH, frequency of storm events and how they affect a wide variety of ecosystem services. We will describe how these efforts can be integrated into Bayesian network relative risk models that include utility nodes. These constructs can be used to describe the trade-offs of different management options in a way to inform adaptive management.

**120 PRESCRIBE: Online Database and Mobile Application for protection of endangered species from pesticides**

*L. Moreno, C.A. Bilheimer, California Dept. of Pesticide Regulation / Endangered Species Program*

The California Department of Pesticide Regulation (DPR) has worked with local stakeholders to develop an endangered species protection program that is comprehensive in scope and includes all federal- and state-listed species and all pesticides registered in California. The core of DPR's program is a free, Web-based database application that allows pesticide applicators and others to identify local habitat for endangered animals and plants, and advises applicators on required use limitations when necessary. The system is called PRESCRIBE, acronym for "Pesticide Regulations Endangered Species Custom Real-time Internet Bulletin Engine." PRESCRIBE (http://cdpr.ca.gov/docd/es/prescint.htm) contains location records for over 1,000 endangered, threatened, and other special status species, encompassing almost 80,000 unique land sections. It also can search for 30,000 pesticides by brand name. In a PRESCRIBE query the user selects the county-township-range-section(s) where he/she intends to apply pesticides and then the pesticide intended for use. The database application looks up the species that occur in the selected section(s) and the active ingredients in the selected pesticides and generates a report of what listed species occur in the area and what use limitations may apply to the selected pesticides for protection of those species. These use limitations were derived from biological opinions developed by the U.S. Fish and Wildlife Service (USFWS) in consultation with the U.S. Environmental Protection Agency (USEPA) and reviewed by USFWS. The endangered species section-habitat index is derived from the Department of Fish and Wildlife (DFW) Natural Diversity Database, as well as maps obtained from USFWS and National Marine Fisheries Service (NMFS). The use limitations are voluntary, unless required by pesticide labeling or pesticide use permits. At the same time, DPR provides pesticide users with training that includes educational materials to help them identify endangered species habitats and pesticide-specific use limitations. PRESCRIBE Mobile, a new mobile application (https://mobile.cdpr.ca.gov/prescribe) also yields protective measures and adds a feature that uses a smart phone's geographic locator function to identify a user's current location and proximity to listed species' habitat.

## Epigenetics and Environmental Exposures: Mechanisms and Effects from Invertebrates to Fishes

**121 Oil and hypoxia induced alterations to DNA methylation patterns in developing sheepshead minnows (*Cyprinodon variegatus*)**

*E. Jones, The University of Southern Mississippi / Coastal Sciences; D. Simning, NCASI / Coastal Sciences; R.J. Griffitt, University of Southern Mississippi / Coastal Sciences*

It is increasingly evident that early-life stress alters the establishment of epigenetic marks. In particular, developmental exposure to toxicants or adverse environmental conditions can alter normal patterns of DNA methylation and have persisting effects on the regulation of gene expression. However, the extent to which these factors interact to modify epigenetic programming remains largely unknown. During the 2010 Deepwater Horizon (DWH) oil spill larval estuarine fish were simultaneously exposed to both polycyclic aromatic hydrocarbon (PAH) contaminants and hypoxia. We investigated how these stressors act individually and in combination to modulate the establishment of DNA methylation marks in developing sheepshead minnows (*Cyprinodon variegatus*). We exposed larval sheepshead minnows (4 days post-hatch) to oil, hypoxia, or both for 48 hours followed by 48 hours of depuration in clean, normoxic conditions. DNA immunoprecipitation coupled with high-throughput sequencing (MeDip seq) was used to identify differentially methylated genes among treatments. We performed pathway analysis on identified genes to predict the biological impacts of differential methylation and compared the results of our methylation analysis with

RNAseq to examine the relationship between promoter methylation and gene expression patterns. This is the first study to examine DNA methylation changes induced by the combination of exposure to DWH oil and environmental stressors. Because DNA methylation patterns can persist throughout the lifetime of an organism, our data provide insight into whether oil-induced changes in gene expression might be permanent due to alteration of epigenetic profiles, and will enhance our understanding of the long-term individual and population level effects of oil and hypoxia exposure.

**122 Deciphering the epigenetics mechanisms underlying the transgenerational bone toxicity of Benzo[a]pyrene**

*F. Seemann, Texas A&M Corpus Christi / Department of Biology and Chemistry; J. Mo, City University of Hong Kong; B. Guo, Hong Kong Baptist University; C. Jeong, Sungkyunkwan University; M. Wan, D.R. Peterson, City University of Hong Kong; G. Zhang, Hong Kong Baptist University; C.W. Winkler, National University of Singapore; J. Lee, Sungkyunkwan University / Department of Biological Science; D.W. Au, City University of Hong Kong / Department of Chemistry*

Recent studies have raised the awareness that Benzo[a]pyrene (BaP) is an transgenerational toxicant with the potential to affect fish bone tissue integrity in the unexposed offspring (< F3). Using the medaka, a fish model established for human skeletal diseases, we demonstrated that ancestral exposure to environmentally relevant levels of BaP resulted in vertebral deformity in the F1-F4 descendants. Increased occurrence of dorsal-ventral compression of vertebra segments was found in the unexposed F1-F4 larvae. A decrease in bone thickness was persistent in the adult F3and F4 BaP lineage. The use of the col10:gfp/osx:mcherry transgenic medaka fish and histological tissue analysis revealed a reduction of osteoblast abundance in the F1-F3 larvae. Deregulated expression of osteogenic key genes pointed towards an impairment of osteoblast differentiation (larvae) and osteoblast activity (adult), which might be causative for an increased bone fragility. BaP-induced epigenetic changes were evident by significant changes in the immunohistochemical expression of histone methylation (H3K4me2, H3K27me2) in bone lining cells as well as the global DNA methylation patterns in F3 larvae and F2 sperm (BaP vs CTL). The antagonistic expression of conserved bone miRNAs with their target bone genes in F3/F4 vertebrae (by qRT-PCR) led to the identification of five functional pairs of mRNA/miRNA in the ancestral BaP exposed medaka. The results shed light on the potential target genes for BaP-mediated epigenetic inheritance, which warrant further investigation. From an ecotoxicological perspective, abnormal skeletal integrity renders the fish more susceptible to bone fractures and exerts a far-reaching impact on individual fitness and survival. Re-assessment of the ecological risk of BaP is urgently needed. The molecular pathways for bone formation and metabolism are highly conserved in vertebrates. The results obtained in the medaka model may allow extrapolation on the potential transgenerational epigenetic mechanisms of BaP on skeletal disorders in other vertebrates, including mammals.

**123 Differential Expression of microRNAs in Fathead Minnow Larvae Exposed to Ethinyl Estradiol**

*G. Toth, D.L. Lattier, D.C. Bencic, M.S. Kostich, R.W. Flick, USEPA / ORD / NERL / EMMD; A.D. Biales, USEPA / ORD / NERL / EMMD / IEIB*

Reduction of uncertainty in stressor-induced exposure assessments relies on characterization of a number of molecular processes that are easily measurable, can be integrated with other process indicators, and ultimately relate to changes in apical endpoints. In both human and ecological model organisms, study of changes in expression of mRNA transcripts has dominated this characterization of molecular processes. However, microRNAs (miRNAs), which are small non-coding RNA molecules, function in RNA silencing and post-transcriptional regulation of gene expression and offer another, potentially toxicologically integratable, window into exposure- and effect-related molecular pathways. Here, methods for analysis of small ribonucleic acids, 20-40 nucleotides in length (smRNA-seq) were used to study differential expression of miRNAs in fathead minnow (*Pimephales promelas*) larvae exposed to 10 ng/l 17a-ethinyl estradiol for 48 hours in static exposures (10 control; 10 exposed samples). The program miRDeep* was used with pooled smRNA reads and a very recent draft of the FHM assembly (n50 of ~300,000) to identify both known and novel miRNA species. Comparisons showed 122 miRNAs to be identical to miRNAs reported for *Danio rerio* reported at miRbase.org. Adapter-trimmed reads from individual samples were then mapped using Bowtie1 to the identified FHM miRNAs to yield sample feature counts. Feature counts were further filtered to yield sample count matrices with consistent levels of non-zero expression across samples. This will be among the first reports of differential miRNA expression in response to an environmental toxicant in *D. promelas*.

**124 Transgenerational effects of early life stage exposure to endocrine disruptors across biological scales in a euryhaline model fish**

*S.M. Brander, B. DeCourten, Oregon State University / Department of Environmental and Molecular Toxicology; J. Forbes, N.P. Burns, H. Roark, University of North Carolina Wilmington / Biology and Marine Biology; M. Settles, University of California Davis / Genome Center; J.W. White, Oregon State University / Department of Fisheries and Wildlife; A.C. Mehinto, Southern California Coastal Water Research Project / Toxicology; R.E. Connon, University of California, Davis / Anatomy, Physiology & Cell Biology / School of Veterinary Medicine*

Emerging research demonstrates that endocrine disrupting compounds (EDCs), which agonize, antagonize, and / or synergize the effects of endogenous hormones, can cause deleterious effects in adulthood as a result of early-life exposure, as well as transgenerational effects. A paucity of studies exist in non-model species, such as *Menidia beryllina*, a euryhaline fish with short generation time that is found throughout North America and is demonstrated to be sensitive to contaminants. We exposed *Menidia beryllina* embryos (8 hpf) until 21 dph to environmentally relevant concentrations of an androgenic and estrogenic EDC of emerging concern: levonorgestrel (Levo) (10 ng/L), bifenthrin (Bif) (5 ng/L), respectively, and coupled this exposure with testing of an established androgenic and estrogenic EDC: trenbolone (TB) (10 ng/L), and ethinylestradiol (EE2) (5 ng/L), respectively. We evaluated the potential for transgenerational EDC effects in three generations across biological scales, with EDC exposure isolated to the parental generation (to 21 dph) only. We investigated changes in gene expression, DNA methylation, gonad histology, fecundity, sex ratio, morphology, and immune response. We also sequenced the *M. beryllina* genome using 10X genomics to facilitate DNA methylation analysis. F0 results show that early-life exposure to EE2 significantly skewed adult sex ratios (feminized) relative to controls. Findings from the F0 and F1 generations demonstrate that exposure to EDCs increased growth in the parental larvae, and that androgenic treatment groups (Levo, TB) maintain this growth through the subsequent F1 generation. In the F0 adults, differences in immune response are apparent between bifenthrin and levonorgestrel, and this pattern is stronger in F1 adults, with significantly greater T-cell proliferation in bifenthrin-exposed individuals relative to controls. Bifenthrin-exposed parental females have increased atretic follicles, and developmental defects are more pronounced in F1 embryos and larvae relative to parents. Transgenerational effects are evident in the unexposed F2 generation, with reduced survival in three treatments (Levo, TB, EE2), altered growth (EE2), and increased craniofacial deformities (Levo). Elucidation of the molecular mechanisms contributing to these higher order effects will inform adverse outcome pathways, as well as allow for the quantification and comparison of responses to established and emerging endocrine disruptors.

**125 Characterization of methylation changes and ERα gene expression as a result of EE2 exposure in fathead minnow liver**

*J. Fetke, University of Cincinnati / Department of Biological Sciences; R.W. Flick, USEPA / ORD / NERL / EMMD; M. See, USEPA / National Exposure Research Laboratory; E. Pilgrim, USEPA / NERL Ecological Exposure Research Division; J. Martinson, USEPA; A.D. Biales, USEPA ORD / NERL / EMMD / IEIB*

Estrogens present in the environment can interfere with endocrine function and cause decreased fecundity, fitness, and sperm production in fish, as well as feminization of male fish. Physiological effects and alterations of gene expression resulting from estrogen exposure have been thoroughly described in fish. Despite this, little is known about epigenetic alterations, although these changes are believed to provide the critical linkage of gene expression with the development of adverse effects at higher biological levels. This study investigates alterations of DNA methylation of the *estrogen receptor α* (*ERα*) in liver tissue in fathead minnows (*Pimephales promelas*) exposed to either 2.5 ng/L or 10 ng/L of the synthetic exogenous estrogen, 17α-ethynylestradiol (EE2). Methylation differences were assessed across all CpG sites in a 2.5KB region encompassing exon 1 and 1.5KB upstream of the start site of the *ERα* gene by targeted deep sequencing of bisulfite treated DNA isolated from treatment groups. Additionally, DNA methylation was assessed from fish depurated for 7 and 14 days to determine the kinetics of methylation. Finally, relationships between *ERα* methylation status and gene expression for individual fish were evaluated. Results from this work will provide information regarding the drivers of response to estrogens and the linkage between alterations in methylation status and gene expression.

**126 Transgenerational Inheritance of Atrazine-induced Reproductive Dysfunction by the Third Generation of Medaka (Oryzias latipes)**

*J.A. Cleary, University of North Carolina at Greensboro / Biology; F.S. vom Saal, University of Missouri Columbia / Biological Sciences; D.E. Tillitt, US Geological Survey / Columbia Environmental Research Center; R. Bhandari, University of North Carolina at Greensboro / Biology*

Epigenetic transgenerational inheritance of altered phenotypes are initiated in aquatic organisms by exposures to some endocrine disrupting chemicals. Currently, little is known about the mechanisms or the significance of such effects on wild populations. Atrazine exposure alters key hypothalamus-pituitary-gonad (HPG) endocrine pathways in fish, a potential mechanism for alteration of the epigenome during development. However, atrazine-induced transgenerational inheritance of reproductive effects in fish has not been investigated. The present study examined the effects of early developmental atrazine exposure on transgenerational reproductive dysregulation in Japanese medaka (*Oryzias latipes*). F0 medaka were exposed during the first twelve days of development (5 or 50 ug/L atrazine, 2 or 50 ng/L 17α-ethinylestradiol (EE2), or solvent control) with no subsequent exposure over three generations. This exposure overlapped with the critical developmental window period for embryonic germ cell development, gonadogenesis, and sex determination. Exposed males and females of the F0 treatment lineages were bred to produce the F1 generation, and this was continued through the F3 generation. Sperm parameters and gonadosomatic and hepatosomatic indices were unaffected in the F0 generation treatment lineages. Hepatosomatic index was reduced in F2 females from either EE2 or atrazine treatment lineages. Fecundity was unaffected by atrazine or EE2 in F0 through F2 generations; however, fertilization rate was decreased in low atrazine and EE2 treatment lineages in the F2 generation. There were significant transgenerational differences in expression of the genes involved in steroidogenesis and DNA methylation. Early life exposure to atrazine didn't cause significant adverse effects in the immediate generation (F0); however, alterations of HPG pathways may pose reproductive risks in future generations of fish.

**127 Developmental methylmercury induces epigenetic alterations in adult zebrafish and in future generations**

*M.J. Carvan, University of Wisconsin-Milwaukee / School of Freshwater Sciences; J.J. Carvan, University of Wisconsin-Milwaukee; R. Klingler, University of Wisconsin Milwaukee / School of Freshwater Sciences*

Developmental exposure of zebrafish to MeHg alters their neurobehavior in a manner similar to other vertebrates. We investigated the direct and transgenerational effects of MeHg, at tissue doses similar to those detected in exposed human populations, on sperm epimutations (i.e., differential DNA methylation regions [DMRs]), neurobehavior (i.e., visual startle and spontaneous locomotion), and transcriptomics in zebrafish. F0 generation embryos were exposed to MeHg (0, 1, 3, 10, 30, and 100 nM) for 24 hours ex vivo. F0 populations were reared to adults and bred to yield the F1 generation lineages, which created the F2 generation lineages. Direct exposure (F0) and transgenerational actions (F2) resulted in hyperactivity and visual deficit in the unexposed descendants (F2) of the MeHg-exposed lineages compared to control. An increase in F2 sperm epimutations was observed relative to the F0 generation with DMRs in genes associated with neuroactive ligand-receptor interaction and actin-cytoskeleton pathways, which correlate to the observed neurobehavioral phenotypes. Developmental MeHg-induced epigenetic transgenerational inheritance of abnormal neurobehavior is correlated with sperm epimutations in F2 adult zebrafish. Further study of the transgenerational health effects of MeHg is required to better understand the risks for human and wildlife populations, which, if transgenerational effects are ignored, are dramatically underestimated.

**128 Consequences of cadmium-induced epigenomes on mutation, animal fitness, and adaptation**

*J. Shaw, Indiana University / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; C. Jackson, R. Keith, S. Glaholt, Indiana University / School of Public and Environmental Affairs*

There is a pressing need to understand how environmental conditions, including toxicant exposure, influence genome content, structure, and function and, in turn, how individuals and populations cope with changing environments. It is now understood that genomes are more than static, heritable, biological templates, but rather display a wide range of plasticity that is modulated by the environment. These environmental perturbations of the genome are functionally important as we are quickly learning that they contribute significantly to variation in individual physiologies, fitness, dynamics of populations, and influence adverse outcomes. Both base-substitution and structural mutations are known to contribute to genome plasticity. While mutation is a stochastic event, mutation hotspots exist both within and between genomes. The genetic events that give rise to mutation (e.g., altered DNA damage/repair pathways, miscued replication, recombination error, transposable elements) are beginning to be defined in terms of their functions, yet little is known of the mechanisms that destabilize DNA, potentiate mutation, and coordinate mutation within the genome. In this talk, long term Daphnia mutation accumulation lines, which exclude selection, are used to test the hypothesis that environmental stress influences epigenetic states including histone modifications, which control access to the genome and affect organismal fitness by potentiating mutations. We report that cadmium induces histone modifications that signal active transcirption, shift nucleome occupancy, and change the distribution of mutations by increasing the their frequency within exons. Understanding these processes will have profound implications for society and the long-term health of populations, which are living longer in the presence of a large and growing diversity of chemicals that can modify DNA.

## Fate and Effects of Metals – Mechanisms of Bioavailability and Toxicity

### 129 Role of geochemical speciation and mineralogy on metal bioavailability

*K. Campbell, M.N. Croteau, US Geological Survey; C. Fuller, US Geological Survey / National Research Program Western Branch; D.J. Cain, US Geological Survey / Water Resources Division*

The geochemical environment is a critical control on metal mobility and bioavailability when contaminants are released to freshwater systems. We show how integrating geochemical modeling, mineralogy, and bioavailability assessment using a model species in laboratory experiments can elucidate the relative importance of exposure pathways (aqueous vs dietary exposures) as well as the difference in bioavailability among solid phases such as metal sorbed to iron oxyhydroxides and pure mineral precipitates. Aqueous complexation with inorganic (e.g., carbonate) and organic (e.g., dissolved organic carbon) ligands can affect metal adsorption onto mineral surfaces as well as mineral solubility, controlling the distribution of metal between the aqueous and solid phase. Complexation also affects the bioavailability of metals to aquatic organisms. For instance, previous work has shown that carbonate complexation can limit the bioavailability of uranium in surface waters with moderate hardness. Geochemical modeling showed that >99% of dissolved uranium was complexed to inorganic carbon in a surface water with a moderate hardness. In addition, uranium complexation with dissolved organic matter has been shown to decrease the bioavailability from the aqueous phase, but had no detectable effect on uranium bioavailability from solid phases. A detailed understanding of geochemical speciation, mineralogy, and associations with dissolved organic matter is important to understanding the bioavailability of metals, including uranium, copper, zinc, and lead. Applying this integrated approach to complex environmental systems with elevated metal concentrations, such as lead-containing mill tailings, can advance our understanding of the geochemical controls on bioavailability.

### 130 Mercury species bioavailability and effects to green alga *Chlamydomonas reinhardtii*

*R. Beauvais-Flueck, University of Geneva; N. Regier, University of Geneva / Department Forel Earth and Environmental Sciences; C. Cosio, University of Reims Champagne-Ardenne / Department F.A. Forel of Environmental and Aquatic Sciences; V. Slaveykova, University of Geneva / Département F.-A. Forel des Sciences de l'Environnement et de l'Eau*

Based on the extensive research over the past 30 years, bioavailability is accepted as a key concept allowing to quantitatively relate the changes in the trace metal concentrations and speciation with the intensity of the induced biological effects. However, in the case of mercury the interactions at ambient medium-biota interfaces are not fully understood, and the interconnection between the mercury speciation, bioaccumulation and biological effects is still to explore. Present work focusses on the bioavailability of inorganic mercury (IHg) and monomethylmercury (MeHg) to model phytoplankton specie *Chlamydomonas reinhardtii*. The interactions of IHg and MeHg with green alga *C. reinhardtii* during short-term exposure to IHg (20pM to 100nM) and MeHg (10 pM to 50nM) were characterized by determining the amount of accumulated IHg and MeHg and the differential gene expression. Accumulated IHg and MeHg were determined w/o cysteine washing to assess the total and intracellular Hg contents. Results revealed a linear increase of the intracellular IHg and MeHg contents in *C. reinhardtii* with the exposure concentration range. The number of dysregulated transcripts determined by RNAseq raised proportionally to the increase of the intracellular Hg contents of both IHg and MeHg. However for the comparable intracellular content, the number of the dysregulated transcripts was higher for MeHg than for IHg, suggesting stronger impact of MeHg on algae as compared with IHg. At transcriptome level, exposure to MeHg dysregulated the expression of genes involved in motility, energy metabolism, lipid metabolism, and transport and antioxidant enzymes in *C. reinhardtii*, while IHg induced similar alterations but only at highest exposure concentration of 100nM. MeHg induced increase of the percentage of the cells experiencing oxidative stress, while no oxidative stress was detected for IHg exposure. The expression of several metal transporters' genes (e.g. Cu, Co, Zn) and aminoacids was affected by both species, finding that was in agreements with the performed competition experiments. The results of this basic research contribute to significant improvement of the understanding of Hg compounds uptake mechanisms and the adverse outcome pathways in green algae, a model of aquatic primary producers, as well as to the development of sensitive genetic biomarkers in support to biomonitoring efforts of mercury monitoring programs in aquatic systems.

### 131 Using advanced speciation techniques to determine the bioavailability of thallium, in rainbow trout (*Oncorhynchus mykiss*) and *Daphnia magna*

*A. Nagel, University of Alberta / Renewable Resources; C. Cuss, University of Alberta; C.N. Glover, Athabasca University; G. Goss, University of Alberta / Biological Sciences; W. Shotyk, University of Alberta / Renewable Resources*

The toxic fraction of waterborne metals is functionally defined as that which passes through a 0.45 µm filter; however, it is understood that this fraction includes metal binding particles which effect bioavailability and toxicity to aquatic biota. Using Asymmetric Flow Field Flow Fractionation (AF4) under ultraclean metal free conditions, the dissolved fraction can be further discriminated, facilitating the identification and quantification of the truly toxic fraction. In this study we analyzed the chemical speciation of thallium (Tl), a trace element associated with the mining of sulfide ores (Pb, Fe, Zn, and Cu). Thallium speciation was assessed concurrently with Tl toxicity to rainbow trout (*Oncorhynchus mykiss*) and the water flea (*Daphnia magna*) under different water chemistries. The mechanism of Tl toxicity was assessed using oxidative stress and ion transport endpoints, and bioaccumulation was related to chemical speciation. Our results suggest that Tl is a metal for which the dissolved ionic fraction is a good proxy for the toxic fraction.

### 132 Accumulation and bio-reactivity of copper and silver complexes in the rainbow trout gut cell line (RTgutGC)

*M. Ibrahim, M. Minghetti, Oklahoma State University / Integrative Biology*

Metal toxicity in aquatic organisms is greatly affected by the chemistry of the water in which they are dissolved. Processes like complexation of metals with inorganic and organic ligands may affect metal toxicity, accumulation, and biological responses (or bio-reactivity). In general, it is believed that only the free ionic forms of metals are bioavailable and metal complexes are not. However, recent studies have suggested that metal complexes may become bioavailable and elicit toxicity. Thus, bioavailability of metal complexes need to be investigated further. Chloride is an important inorganic ligand that forms complexation with metals. Due to its anionic nature, changes in chloride concentration might influence the speciation of metals and consequently their toxicity, accumulation, and bio-reactivity in organisms. In this study, we have tested this question by preparing different synthetic media of varying chloride concentration (0- 146 mM $Cl^-$). Metal speciation of each media was conducted using Visual MINTEQ, a chemical equilibrium software. Ionic $Ag^+$ was dominant in medium with 0 mM $Cl^-$, neutral complex (AgCl) dominated in 1-10 mM $Cl^-$ media, and negatively charged Ag complexes (mainly $AgCl_2^-$) were dominant from 10-146 mM $Cl^-$ media. Copper speciation remained stable across the chloride concentration gradients, mainly complexing to hydrogen phosphate(~42%) or remained in ionic form, $Cu^{2+}$ (~43%). Using the Rainbow trout gut cell line (RTgutGC) as a model, cytotoxicity of $AgNO_3$ and $CuSO_4$ dissolved in the different synthetic media were conducted using two dyes: alamarBlue (indicator of metabolic activity) and CFDA-AM (indicator of cell membrane integrity). In cells exposed to copper, metabolic activity decreased significantly at higher chloride concentrations. Ag toxicity resulted to be more tolerant

at intermediate concentrations (1 to 10 mM) and more toxic in $Cl^-$ free medium and high $Cl^-$ media 25-75 mM $Cl^-$. To investigate metal accumulation and bio-reactivity (metallothinein mRNA levels), cells will be exposed to 500 nM (below NOEC) and LOEC concentrations of each metal dissolved in respective media. Accumulation and bio-reactivity of copper and silver will be determined by ICP-MS and by measuring metallothionein mRNA levels, respectively. This study will shed light on understanding the bioavailability of metal complexes, especially for Ag complexes.

**133 Metal Bioaccumulation and Biomarker Responses in Oysters Exposed to Contaminated Sediments and Hypoxia**

*B. Khan, National Research Council of the National Academies / USEPA Atlantic Ecology Division; A.H. Ringwood, UNC-Charlotte / Department of Biology*

Heavy metal pollution along with fluctuations in dissolved oxygen (DO), pH, salinity, and temperature are major challenges faced by coastal and estuarine organisms. While hotspots of high metal concentrations are limited, many coastal areas have low to moderate levels of contaminants. Many of these areas are also characterized by low DO (hypoxia), which are expanding worldwide due to global warming. Both hypoxia and metals can induce oxidative stress in aquatic organisms via cellular production of reactive oxygen species, and interactions between them can exacerbate oxidative stress. Metal ions can exist in the environment complexed with organic or inorganic matter, and their bioavailability can be affected by water quality parameters such as DO and pH. The overall goal of these studies was to evaluate the effects of hypoxia on metal uptake (Cu, Zn, Mn, Fe) and subsequent toxicity in tissues of Eastern oysters, *Crassostrea virginica*. Oysters are valuable bioindicators of habitat health and play critical roles in maintaining ecosystem integrity. Oyster tissue metal concentrations (gills and hepatopancreas) were measured after four- and eight-day exposures to moderately contaminated sediments under different hypoxic conditions to assess metal uptake. Cellular biomarker responses of oxidative stress were also evaluated (lipid peroxidation to evaluate tissue damage, and total glutathione concentrations for antioxidant status). Increases in gill metal concentrations were found to be related to DO and pH of overlying water indicating that environmental hypoxia can potentially affect metal bioavailability; and oxidative stress was observed. While there were significant correlations between tissue metal levels and biomarker responses, tissue-specific differences were observed. Glutathione levels in gills decreased with increasing Cu and Zn burdens, but increased in hepatopancreas. These studies demonstrate the bioaccumulation of metals from moderately contaminated sediments and the potential effects of hypoxic conditions on bioavailability, as well as the relationships between tissue metal concentrations and cellular biomarker responses of oxidative stress. These studies also demonstrate the value of cellular biomarkers for identifying potential risks of the complex interactions between sediment metals and other environmental parameters that can affect bioavailability and organismal health, and ecosystem sustainability and resilience.

**134 The Influence of Acidification and Copper Exposure on Copper Accumulation and Physiological Responses in the Pond Snail, *Lymnaea stagnalis***

*G.K. Bielmyer-Fraser, F. Alip, R. Adeyemi, N. Carney, F. Santiago, K. Siemens, Jacksonville University / Chemistry*

Atmospheric carbon dioxide ($CO_2$) is rising at an accelerated rated due to various anthropogenic activities. Ocean acidification has recently received much attention; however, effects of $CO_2$ in freshwater environments are less understood. Land-based sources of pollution, such as metals, have also been a noted problem; however, little research has addressed combined exposure of both pollutants to sensitive, calcifying organisms. This study examined copper accumulation and activity of anti-oxidant enzymes, catalase and glutathione peroxidase, in the freshwater common pond snail, *Lymnaea stagnalis,*after exposure to increased $CO_2$ and copper. Results from this experiment demonstrated increased copper accumulation in snails exposed to copper; however, exposure to increased $CO_2$ did not increase the magnitude of copper accumulation. Increased glutathione peroxidase activity was observed as a consequence of $CO_2$ and copper exposure individually, with a greater response in $CO_2$-exposed snails. This study provides insight into mechanisms of toxicity from exposure to multiple contaminants in *L. stagnalis.*

**135 Feeding strategies of stream invertebrates: Linking resource selectivity to metal exposure and uptake**

*T.M. Short, US Geological Survey; M. Hornberger, US Geological Survey / Water Resources Division; R. Keating, US Geological Survey*

Previous studies have shown that life-history strategies are strong determinants of contaminant exposure in stream invertebrates, and that trophic status and feeding behavior are key factors affecting exposure risk. In this study, we examined the importance of resource subsidies (periphyton and seston) as metal sources to invertebrate consumers in a mining-impacted river. Metal concentrations in periphyton and suspended particulates were compared to spatial patterns of metal bioaccumulation in invertebrate primary and secondary consumers. Periphyton was highly efficient in assimilating aqueous metals with uptake rates greatest during early stages of growth and biomass accrual. Examination of invertebrate metal bioaccumulation in relation to feeding trait affinities showed that metal uptake increased markedly in taxa that included periphyton as part of their diet. Similarly, metal concentrations in seston were highly correlated with tissue concentrations in filter-feeding invertebrates ($r^2$=0.74) where filtering comprised >40% of a taxon's food acquisition strategy. Metal bioaccumulation in invertebrates was largely independent of seston transport rates and organic-inorganic composition. Results of gut content analyses will be used to further identify source contributions to metal exposure, and to refine a biodynamic model describing metal uptake and loss kinetics in metal enriched environments.

**136 Uranium uptake in aquatic insect larvae and its loss through insect metamorphosis**

*B. Henry, US Geological Survey / Biology; D. Walters, USGS / Fort Collins Science Center; M.N. Croteau, US Geological Survey; D.J. Cain, US Geological Survey / Water Resources Division; J. Miller, US Geological Survey / Fort Collins Science Center; B. Crone, U. Karst, University of Muenster*

In 2012, the Department of Interior issued a twenty-year moratorium on uranium (U) mining in federal lands of the Grand Canyon Region, allowing for study of the impacts that this activity has on water and wildlife resources. The Colorado River watershed contains several tributaries that receive U inputs naturally from the land that they drain, and understanding the effects of U on aquatic biota is crucial to understanding the risk of potentially increased U introduction through mining. Aquatic insects create a vital link between aquatic and terrestrial ecosystems. They can carry their contaminant history with them as they metamorphose to become adults, transferring exposure risks to terrestrial consumers, but this varies widely by contaminant. To better understand accumulation and transfer of U to across metamorphosis, we exposed a laboratory mayfly species, *Neocloeon triangulifer,* to aqueous and dietary U as late-stage larvae through metamorphosis. We collected larvae, pre-emergent nymph (PEN), subimago, and imago staged mayflies and measured whole body U content using inductively coupled mass spectrometry (ICPMS). We also used laser ablation ICPMS (LA-ICPMS) to create heatmaps indicating areas where mayflies store U during each stage. Greater than 90% of the U accumulated in the larval stage was lost by the final adult stage; the bulk of that loss (75%) occurred between the larval and PEN stages while the mayflies are fully aquatic. LA-ICPMS qualitatively indicated slight changes in the storage of U from stage to stage within mayflies. The LA-ICPMS showed a loss of U between imago (egg-bearing) and post-partum imago stages, suggesting an additional loss of U through maternal transfer. These findings mirror results from a wide-ranging field collection of larval and adult blackflies (Simuliidae) in the Colorado River and its tributaries within the Grand Canyon. Mean U concentrations in blackfly larvae ranged over an order of magnitude (0.5 – 5.7 µg/g) among sites, but U in adult blackflies at these sites was typically at or below the method detection limit of 0.03 µg/g at these same sites. These results indicate that aquatic insects are not major vectors of U transport from aquatic to terrestrial environments of the Colorado River, and that the risk of U exposure to terrestrial insectivores is low.

## Monitoring, Remediation and Ecotoxicological Assessment of Emerging Contaminants in Soil and Water

**137 Comparing the chemical fingerprints and predicted estrogenicity of conventional soil amendments to sewage sludge**

*G. Black, University of California, Davis / Agricultural & Environmental Chemistry*

Climate change has affected agricultural practices in both the developed and developing world as farmers and landowners search for more drought-resistant and sustainable practices. Soil amendments like composts and animal manures have been used for decades to replace vital plant nutrients, increase water-holding capacity, and improve soil structure and productivity. Simultaneously, wastewater treatment plants are producing millions of tons of sludges annually, most of which remain vastly underutilized in agriculture yet have the potential to serve as a nutrient-rich amendment. This work compares organic contaminants present in California sewage sludge that has undergone various treatment intensities with conventionally used soil amendments (green waste compost, food waste compost, organic dairy manure and non-organic dairy manure) to better understand the risk associated with agriculture-based land application of sewage sludge. Quantitative LC-QTOF-ESI-MS analysis showed that increasing the robustness of sludge treatment is successful at eliminating some contaminants while concentrating others. Suspect screening identified many common pesticides and pharmaceuticals present throughout all amendments. Non-targeted analysis identified hundreds of unique chemical features dividing the sludge-based samples and the conventional amendments. We coupled an estrogenicity-prediction model (VEGA toxicity prediction) to tentatively assigned non-target features to narrow the chemical identification focus to biologically relevant features. Combining quantitative, suspect and non-target analysis with estrogenicity data provides a comprehensive chemical snapshot of the calculated risk associated with land application of sewage sludge on agricultural systems.

**138 Evaluating Native and Naturalized Plant Species for the Phytoextraction of DDT and Dieldrin at Point Pelee National Park**

*R. Bergin, Queens University / Environmental Studies; B. Zeeb, Royal Military College / Chemistry Chemical Engineering Dept; A. Rutter, Queens University / School of Environmental Studies*

Dichlorodiphenyltrichloroethane (DDT) and dieldrin are organochlorine pesticides that were used in Canada until the 1990's. Both pesticides were sprayed in large quantities and have persisted within soils, water bodies and sediments for decades. Previous agricultural practices have resulted in levels of DDT and dieldrin that exceed Canadian soil quality guidelines at Point Pelee National Park (PPNP). Park staff are seeking remediation strategies to remove these contaminants in a cost-efficient manner, while reducing environmental impact and promoting sustainable practices. Phytoremediation is an environmentally feasible technique that uses natural plant processes to remove contaminants from soil. Previous work identified two areas of PPNP with particularly high organochlorine pesticides contamination, which were then selected as test plots for this study. Nine native and naturalized plant species were evaluated for their effectiveness at extracting organochlorine pesticides from contaminated soils via the process of phytoextraction. Microwave extraction was used to quantify levels of DDT and dieldrin in these species. Preliminary results show that two species, *Andropogon geradii* (big bluestem) and *Bromus inermis* (smooth brome), were the most successful at phytoextracting DDT and dieldrin from the contaminated test plots. Phytoextraction using various native species appears to be a viable technology for remediating contaminated sites at PPNP.

**139 Study the Relationship between Physicochemical Parameters of Emerging Organic Contaminants and Plant Uptake in the Presence of Sorbent Materials.**

*A. Mawof, McGill University / Bioresource Engineering; S. Prasher, McGill University Macdonald Campus / Bioresource Engineering; S. Bayen, McGill University Macdonald Campus / Food Science and Agricultural Chemistry*

The demand of freshwater for irrigation is increasing to produce more food for the global human population. In this context, wastewater (WW) irrigation is a common practice in many countries. However, the presence of contaminants such as hormones, pharmaceuticals, and personal care products (PPCPs) in WW may represent a major risk ad these contaminants may be harmful to the environment and human health. In a field lysimeter study (sandy soil), the uptake of hormones [including estrone (E1), 17β-estradiol (E2) Estriol (E3), Ethinylestradiol (EE2) and progesterone], and PPCPs [ DEET, triclosan, diclofenac, ibuprofen, caffeine, and carbamazepine] was studied in potato plants exposed to contaminated WW. The accumulation was studied in different tissues, including stems, leaves, roots, and tubers. compost and biochar were added in specific lysimeter treatments and the translocation of contaminants to potatoes was investigated. In total, six treatments (control, compost, biochar 1%, biochar 3%, biochar 1% + compost, and biochar 3% + compost,) were tested in triplicate. The results are discussed in the context of the physicochemical parameters (such as water solubility, octanol-water partition coefficient, and acid dissociation constants) of organic contaminants.

**140 Selected polychlorinated biphenyls (PCBs) congeners and dichlorodiphenyltrichloroethane (DDT) in fresh root and leafy vegetables**

*O.S. Olatunji, University of KwaZulu-Natal / School of Chemistry and Physics*

Persistent organic pollutants (POPs) are dangerous and toxic pollutants reckon to cause adverse effects on human and animal health, including death. POPs such as polychlorinated biphenyls (PCBs) and pesticides are subtly released into the environment from industrial and agricultural use. Global circulation is due to their trans-boundary transport capacity, contingent on aerodynamic and hydrological properties. Plants have capacity to take-up POPs, and these bio-magnify along heterotrophic transfer pathways. In this study, levels of selected 6-PCB congeners and 3- DDTs in some leaf and root vegetables were investigated. Leaf and root vegetables were collected from different horticultural farms areas in Cape Town. The 6-PCBs and 3-DDTs were recovered from the samples using solid phase extraction(SPE), followed by GC-MS analysis. The ∑PCBs and ∑DDT (on-whole basis), were ranged: 90.93-233.87 µg/kg and 38.92-66.14 µg/kg respectively. The 3-PCBs and 6-DDTs levels were slightly higher in leaf vegetables compared to root vegetables. The detection of PCBs and DDTs in the vegetables suggest the probable use of PCBs containing pesticides. Although the observed concentrations were below the WHO maximum residue limits, consumption of such contaminated leaf and root vegetables portend a health risk.

**141 Remediation of polycyclic aromatic hydrocarbons (PAHs)-contaminated soil using activated carbon supported bimetallic particles-activated persulfate**

*T. Huifang, Beihang University; Y. Liang, Beihang University / School of Space and Environment; J. She, California Department of Public Health / Environmental Health Laboratory Branch; Y. Sun, Beihang University / California Department of Public Health / School of Space and Environment / Environmental Health Laboratory Branch*

With the development and growth of several industrial activities, polycyclic aromatic hydrocarbons (PAHs) have appeared and accumulated in soils and groundwater. Recent years, PAHs have become one of the major contaminants in the world because of their typical features of low solubility, eco-toxicity, mutative and carcinogenic to human. Chemical oxidation is a promising technology for the remediation of soils contaminated with PAHs. In this study bimetallic materials supported on activated carbon (AC) were synthetized to activate persulfate for the degradation of 19 kinds of PAHs, such as Naphthalene (NAP),2-Methylnaphthalene (2-MET), Acenaphthylene (ANY), Fluorene (FLU), Phenanthrene (PHE), Anthracene (ANT), Fluoranthene (FLT), Pyrene (PYR), Benzo(a) anthracene (BaA), Chrysene (CHR), Perylene (PER), Benzo(b)fluoranthene (BbF), Benzo(k)fluoranthene (BkF), Benzo(e)pyrene (BeP), Benzo(a) pyrene (BaP), Indeno(1,2,3-cd)pyrene (IPY), Dibenzo(a,h)anthracene (DBA), Benzo(g,h,i)perylene (BPE). Five kinds of bimetallic catalysts, including AC-supported metal such as Fe, Fe/Cu, Fe/Ni, Fe/Pd and Fe/Pt were synthesized by liquid phase reduction method. The characterization by Brunauer-Emmett-Teller (BET) and X-ray diffraction (XRD) showed that the prepared composites have larger specific surface area, higher intensity and high loaded on AC of bimetallic materials. Temperature, reaction time were studied to observe the removal efficiency of 19 kinds of PAHs from soil-water system. Higher PAHs removal efficiencies were achieved when Fe-AC was used as activator, the removal efficiency of NAP, PER orBbF was about 60%~70%, while other 16 kinds of PAHs showed higher resistance to oxidation, achieving 80%~100% removal after 72 h combined with heating (50?). When use AC-Fe/Ni as activator, 17 kinds of PAHs was completely removed except PER orBbF. Similar results were obtained when activation was AC-Fe/Cu at the same reaction condition. While persulfate was activated by AC-Fe/Pd or AC-Fe/Pt, the removal efficiency of 16 kinds of PAHs showed slightly lower than activators AC-Fe/Ni and AC-Fe/Cu, except that NAP, PER or BbF was near 70%. AC-supportedbimetallic particles-activated persulfate combined with heating process showed higher removal efficiency than persulfateoxidation processes in the remediation of PAHs-contaminated soil. Taking into account the high removal efficiency and the acceptable remediation times the technology is suitable for its aimed purpose.

**142 Survey of Brominated Flame Retardants (PBDE and BB 153) in the Diep and Kuils Rivers, Cape Town, South Africa**

*O.S. Fatoki, Cape Peninsula University of Technology / Chemistry; P. Daso, Tshwane University of Technology, Pretoria / Environmental Sciences*

Brominated flame retardants (BFRs) are substances used in plastics textiles, electronic circuitry and other materials to prevent fire. Their presence in the environment are generating increasing concern because of their potential human and ecological health risks. They belong to the group of emerging contaminants and are classified endocrine disruptors. Studies on them are still scanty in South Africa. This study reported the concentrations of PBDE and BB153 congeners in waters and bottom sediments of two rivers in Cape Town, South Africa. There analyses and structural elucidation were done by GC-ECD and GC-TOF-MS, respectively. The results indicated concentrations of BPDEs in the range of 0.06 – 2.47 ng/g in bottom sediments of Diep River while levels were relatively higher in the sediment of Kuils River. Mean concentrations of BB 153 in the Diep River were in the range of ND – 0.39 ng/g while it varied between ND – 1.21 ng/g in the Kuils River. Effluent discharges from nearby wastewater treatment plants were identified as important sources of the PBDEs in the rivers while grey water intrusion could contribute to upstream contamination. The work confirmed the contamination of the water systems with BFRs with potential for ecological and human health effects, especially if the water from the rivers were used for domestic purposes without treatment and the EDCs were not removed or if the waters were used for irrigation purposes in agriculture.

**143 Pollution Characteristics and Ecological Risk Assessment of PFASs in Jiulong River Estuary-Xiamen Bay, China**

*X. Wang, Xiamen University / Department of Environmental Science and Technology; B. Lin, National Institute of Advanced Industrial Science / Research Institute of Science for Safety and Sustaintability; L. Ma, S. Wang, State Key Laboratory of Marine Environmental Science / College of the Environment and Ecology / Xiamen University*

Per- and polyfluoroalkyl compounds (PFASs) are a new type of persistent organic pollutants (POPs) closely concerned by the world. They were detected in various media from many countries include China, one of the major producers of PFASs. Jiu-long river estuary-Xiamen Bay is an important water source in the Xiamen area, China. This paper studied the pollution characteristics and ecological risk assessment of PFASs on Jiulong river estuary-Xiamen bay. The concentrations range of 28 kinds of PFASs (including 13 perfluorinated carboxylic acids (PFCAs), 5 perfluorinated sulfonic acid (PFSAs), and 10 precursors), was 0.34-100.33 ng L-1 in the water with a significant seasonal variation. The PFASs of the surface water in the dry season (12.94-100.33 ng L-1) was much higher than those (0.41-5.88 ng L-1) in the wet season. PFOS was the main medium-chain PFASs, PFBS was the main pollutant of PFSAs, and PFBA, PFPeA, PFHxA were dominant in PFCAs. The PFASs in the sediments of the Jiulong river estuary – Xiamen bay was 4.64-7.42 ng g-1 dw. PFOS was the main pollutant. The adsorption ability of sediment increased as the carbon chain and salinity increased according to the sediment-water partition coefficient. The ecological impact of PFASs was also assessed using AIST-MeRAM model. The results showed that PFASs constituted no ecological threats to the research area so far, measured by the Margin of Exposure (MOE) indicator and Species Sensitivity Distribution method (SSD).

**144 Quantification and probabilistic risk assessment of selected β-lactam antibiotics in the Diep River water samples**

*B. Opeolu, Cape Peninsula University of Technology / Faculty of Applied Sciences; O.S. Olatunji, University of KwaZulu-Natal / School of Chemistry and Physics; R. Chitongo, Cape Peninsula University of Technology Cape Town South Africa / Chemistry*

Pharmaceuticals are widely used in human and veterinary residues. Residues of pharmaceutical compounds have been reported to be present in biological samples and environmental matrices. Occurrence of pharmaceuticals has been linked to many global health and ecological issues. These include antibiotic resistance and endocrine disruption among others. In this study, a method was developed for the measurement of three antibiotics in water samples. The method was used for qualitative and quantitative determination of the three β-lactam antibiotics (amoxicillin, ampicillin and chloramphenicol) in surface water samples collected from the Diep River. Levels of the compounds measured were subjected to probabilistic risk assessment to predict the possibility of exceeding regulatory values. Mean concentrations of quadruplicate samples of water collected in winter and spring months from five sampling points were ranked using Weibull's probabilistic approach and centile rankings. This was employed to examine the likelihood of exceedance of predicted no effect concentrations set by international regulatory agencies. The three β-lactam antibiotics-amoxicillin (AMX), ampicillin (AMP) and chloramphenicol (CHLR) occurred at variable concentrations in the Diep River. The levels detected ranged between < DL – 13.29 µg/L and < DL – 11.55 µg/L in winter and spring respectively for AMX. Corresponding values for AMP were < DL to 1.24 µg/L and < DL – 5.27 µg/L in CHLR was not detected in all water samples analyzed. Results of probabilistic risk assessment of the compounds will be presented.

## Exposure Assessment and Modeling for Ecological Risk Assessment of Veterinary Pharmaceuticals and Pesticides

**145 In vitro Assessment of Pyrethroid Bioaccessibility via Particle Ingestion**

*J. Wang, University of California Riverside; K. Lin, Xiamen University; A.R. Taylor, J. Gan, University of California, Riverside / Environmental Science*

Due to their intensive use in agricultural and residential pest control, human exposure to residues of multiple pyrethroids frequently occurs. Pyrethroids have exceptionally high affinity for solid particles, highlighting the need to understand human exposure through oral ingestion of contaminated soil or dust particles. In this study, we used artificial gastrointestinal fluids to measure the desorption or bioaccessibility of eight current-use pyrethroids in soil and dust samples. Tenax was further included as a sink in parallel treatments to simulate the effect of removal due to transfer of pyrethroids to lipid membranes. The use of 0.4 g of Tenax in 20 mL digestive fluids resulted in rapid and efficient trapping of pyrethroids, and further, greatly enhanced bioaccessibility. In the artificial digestive fluids without Tenax, 6.0-48.0% of pyrethroids was desorbed over 21 h, and the fractions increased by 1.6-4.1 folds to 21.5-79.3% with the Tenax sink. Therefore, 6.0-79.3% of soil or dust-borne pyrethroids may be considered bioavailable upon ingestion. While protein and sucrose increased the estimated bioaccessibility, co-presence of lipid (vegetable oil) decreased the bioaccessibility of pyrethroids, likely due to competitive phase partition. Pyrethroids were also found to be unstable in the artificial intestinal fluid containing pancreatin, further decreasing the potential bioaccessibility of pyrethroids on soil or dust particles. The limited bioaccessibility should be considered to refine the prediction of human exposure and risk through oral ingestion of pyrethroid residues.

**146 The Distribution and Concentration of Antibiotics in Urban Streams, Rural Streams, and Rural Groundwater in the Piedmont of North Carolina**

*A.D. Gray, University of North Carolina at Greensboro / Biology; D. Todd, University of North Carolina at Greensboro / Chemistry; A.E. Hershey, University of North Carolina at Greensboro / Department of Biology*

Classification of pharmaceuticals as "contaminants of emerging concern" has led to numerous studies investigating the ecological impacts of these compounds. Antibiotics are the most widely used pharmaceutical product on the market, leading to much attention due to their role in developing resistant bacteria. Antibiotic pollution in streams is of importance because streams play a crucial role in the transport of water from inland areas to coastal waters as well as to rivers and lakes. The presence of antibiotics in streams demonstrates the capacity for antibiotics to be transferred from inland areas into larger water bodies. Antibiotics entering streams can arise from various sources. In urban areas, antibiotics of human and veterinary origin can enter streams due to runoff or leaching from surrounding areas, but most notably from wastewater discharge that releases effluent directly into streams. In rural areas, antibiotics can enter streams from antibiotic application in the maintenance of livestock, which through runoff and leaching, can contribute to veterinary antibiotics being present in rural streams and groundwater. The interaction between groundwater and surface water provides a mechanism for contaminated water to not just have ecological implications, but also human health implications because groundwater is often the source of rural drinking water. The present study investigated 16 residential rural well sites in Guilford, Alamance, and Randolph County, North Carolina. Along with these 16 well sites we also investigated 16 stream sites in close proximity to these residential properties, and 6 urban streams sites, 3 of below WWTFs and 3 above WWTFs. Mass spectroscopy work with the LTQ Orbitrap instrument detected 13 antibiotics in these compartments over 3 different seasons (fall, winter, and spring). These detected antibiotics have applications that originate from both human and veterinary uses. Results indicate that land use and population are key factors in the distribution of antibiotics in stream ecosystems and that groundwater contamination is of concern due to the role it plays in feeding into stream surface waters and rural drinking wells.

**147 Comparison of OECD 308 and OECD 309 Simulation Studies Investigating the Fate of Human Pharmaceuticals in Water-Sediment Systems**

*J.A. Elmoznino, Pfizer, Inc. / Environmental Sciences PDM*

Simulation studies are fundamental in determining the potential for persistence and for the assessment of risk of exposure. The OECD 308 and 309 Guidelines describe simulation studies designed to assess the biotransformation of distribution behavior in water-sediment systems. Since the European Medicines Agency (EMA) environmental risk assessment (ERA) testing guideline was finalized in June 2006, the OECD 308 Water-Sediment transformation test has been routinely conducted in Phase II Tier A testing for all human pharmaceutical marketing authorization applications. The 308 test design, a stagnant and stratified sediment layer:pelagic river water layer, does not represent a typical wastewater treatment facility discharge into a river, but rather that of an irrigation ditch; a scenario which is considered more applicable to pesticide application. Results from the 308 include half-life values in water, sediment and total system; amount of compound shifting to sediments, and non-extractable residue (NER) formation; identity of transformation products (if >10%); amount of $CO_2$ formation; and total mass balance and distribution in the test system. The OECD 309 "Aerobic Mineralization in Surface Water" guideline defines a simulation study representative of discharge into a moving water system, with a fully aerobic mixed water-suspended sediment test design. Similarly, results from the 309 include total system half-lives; NER formation; identity of transformation products (if >10%); and amount of $CO_2$ formation. For the past several years, Pfizer's strategy has been to include OECD 309 as part of the ERA testing package in order to fully appreciate the potential fate of APIs discharged into natural receiving waters. The aim of this report is to relate the data obtained from OECD 308 and 309 studies for several pharmaceuticals, systematically comparing how they behave in both 308 and 309 water–sediment systems by exploring relationships between biotransformation rate constants, NER formation, and mineralization across the test systems. The goal of this study is to determine if the outcomes from the 28 day 309 study can be used to predict the potential for similar indications of persistence or exposure risk obtained in the 100 day 308 study.

**148 Loading of Pesticides to Wastewater Catchment from Flea and Tick Topical Products**

*J. Teerlink, California Department of Pesticide Regulation / Surface Water Protection Program; Y. Xie, R. Budd, California Department of Pesticide Regulation; T.M. Young, University of California-Davis / Civil and Environmental Engineering*

Flea and tick treatments used on domestic animals contain pesticide active ingredients that serve as a source to wastewater treatment catchments. Pesticides can enter wastewater directly through routine bathing or indirectly through cleaning surfaces the pet has come in contact with such as companion humans, pet bedding, and other residential surfaces. The California Department of Pesticide Regulation (DPR) is working to evaluate the relative contribution of currently-registered flea and tick treatments to total pesticide loading in wastewater catchments and improve registration evaluation and post-use risk assessment modeling capabilities for pet products. DPR conducted a dog-wash study to quantify the fraction of fipronil in spot-on products that washed off during routine bathing of volunteer dogs. Dogs were washed 2, 7, or 28 days post application with an average of 21 ± 22, 16 ± 13, and 4 ± 5 % wash-off respectively. There was measurable fipronil in all samples with a total mass during a single bathing event ranging from 3.6–230.6 mg per dog. A subsequent study measured effluent from a pet grooming operation at the discharge point to a wastewater system and found pesticide active ingredients used in common topical treatments (imidacloprid, permethrin, bifenthrin, cyfluthrin).

The same set of samples was analyzed using nontarget suspect screening by LC-Q/TOF methods. The presence of additional compounds found in ingested products and topically-applied pet treatments were tentatively identified with a high degree of confidence (i.e., not confirmed with a standard). An improved understanding of direct and indirect down-the-drain transport of pet products is essential to develop pre-registration and post-use environmental risk models.

**149 Identification of Herbicide Source Areas and Dominating Transport Processes in a High Agricultural Intensity Catchment**

*M.F. Winchell, H. Rathjens, Stone Environmental, Inc. / Environmental Systems Modeling; R. Sur, Bayer AG – Crop Science Division / Environmental Safety; D. Baets, Bayer AG Crop Science Division / Sustainable Operations; F. Krebs, Dr. Knoell Consult GmbH; D. Lembrich, Bayer AG Crop Science Division*

The occurrence of herbicides in surface waters of intensively cultivated catchments can originate from a variety of sources. These include transport via runoff and erosion during storm events, subsurface transport through lateral flow and through subsurface tile drainages, and from spray drift during applications. The Soil and Water Assessment Tool (SWAT) is widely used in the United States and the EU for catchment scale hydrologic and water quality modeling of non-point source chemicals in the environment. The SWAT model was applied to a 992 ha agricultural catchment in the Flanders region of Belgium to help in better understanding the sources of the herbicide detections observed in daily sampling over 3.5 years at two locations along the catchment's primary stream. The SWAT model was calibrated to observed flow and chemical monitoring data, then used to characterize the relative contributions of herbicides via surface processes, subsurface processes, and spray drift. In addition, very vulnerable fields with significant contributions to surface water exposure were identified. A quantitative comparison between monitoring data and simulated exposure profiles was made to single out those high residue concentrations that could not be attributed to any of these traditionally considered exposure pathways, and could ultimately be only explained by point source contributions. The model results demonstrate that SWAT is capable of simulating streamflow in a small agricultural catchment, and is capable of simulating diffuse source pesticide concentrations. This allowed application of an approach that incorporated model uncertainty analysis in distinguishing between diffuse source dominated high concentrations from those most likely affected by point sources. The SWAT model also proved useful in identifying the spatial variability in the dominant transport processes contributing pesticide residues to the stream. While surface runoff of soluble pesticide was the major non-point source contributor on most fields, lateral subsurface flow was found to be important as well, especially in the western portion of the catchment. Spray drift is likely the least significant contributor at the catchment scale. Overall, the analysis of monitoring data and modeling results shows that the potential for reducing herbicide concentrations in the study catchment can be addressed by mitigating both point source contributions from farmyards as well as diffuse sources.

**150 Modeling environmental exposure to Revalor-XR from beef feedlots and manure-amended crop fields**

*Q. Ma, J.P. Staveley, J. Ma, Exponent, Inc.; C. Celly, Intervet Inc. d/b/a Merck Animal Health; G. Scheef, MSD Animal Health Innovation GmbH / Preclinical Development*

Revalor-XR is an extended-release veterinary drug for implant in steers and heifers that contains trenbolone acetate and 17β-estradiol (17β-E2) as active pharmaceutical ingredients (APIs). As part of the Environmental Assessment (EA) for approval of this drug in the US, a novel exposure assessment was conducted. The focus was on characterizing exposure of surface water due to runoff and leaching from beef feedlots and manure-amended fields, both for generic farm scale and watershed scale for selected watersheds with high-density beef feedlots and manure-amended soils. Both APIs are metabolized in situ resulting in the excretion of 17β-trenbolone (17β-TB), 17α-trenbolone (17α-TB), trendione (TBO) and 17β-E2, 17α-estradiol (17α-E2), and estrone (E1). The relevant environmental fate data for each of the individual compounds determined in laboratory studies were aggregated to generate representative values for the surrogate trenbolone compounds and estradiol compounds. The runoff potential from the feedlots was calculated using the USDA-NRCS' approach accounting for water balance (TR-55 method) and mass balance of the surrogate compounds. The runoff potential from the manure-amended crop fields was evaluated using the USEPA's EXPRESS model. The potential for leaching, both from feedlots and crop fields was evaluated using the USEPA's SCIGROW model. Finally, surface water exposure for selected watersheds was evaluated using USEPA's BASINS model. The generic farm scale exposure assessment demonstrated that the major pathways of exposure were runoff from either feedlots or manure amended crop fields, with leaching pathways being only minor contributors. The exposure assessment of the surrogate compounds on the watershed scale was thus performed by considering the runoff pathways only. The exposure assessments further showed that the concentrations of the surrogate compounds in surface water varied with the generic farm scale scenarios resulting in higher concentrations (runoff from feedlot > runoff manure-amended crop field) compared to the watershed scale scenarios. The assessment at the watershed scale demonstrated that it is highly unlikely that the compounds associated with Revalor-XR would have any significant environmental impacts when used according to the Revalor-XR label. The environmental assessment supported a Finding of No Significant Impact by the U.S. Food and Drug Administration from the use of Revalor-XR in beef steers and heifers in the US.

**151 Model the effectiveness of vegetated filter strips in reducing contaminants in feedlot runoff**

*I. Khanijo, M. Cheplick, D. Merritt, Zoetis; W.M. Williams, A. Ritter, Waterborne Environmental, Inc.*

The National Pollutant Discharge Elimination System (NPDES) regulations require concentrated animal feeding operations (CAFO) with greater than 1000 head beef cattle to contain feedlot runoff in settling basins designed to hold runoff from a 25-year 24-hour rainfall. CAFO with less than 1000 head may discharge feedlot runoff to nearby waters under NDPES permits if there are certain best management practices (BMPs) in place like settling basins or vegetated filter strips. Runoff from feedlots may contain nutrients or veterinary pharmaceutical residues excreted in animal waste, which under some circumstances could be potentially harmful to aquatic organisms if released directly to nearby surface waters. The objective of this presentation is to model the effectiveness of vegetated filter strips (VFS) in reducing contaminants in feedlot runoff using the WINPRZM and VFSMOD models. Effectiveness of VFS in reducing nutrient concentrations in feedlot runoff will be presented as a case study. WINPRZM was enhanced to simulate runoff from an earthen or concrete uncovered beef feedlot. The model predicts the daily edge-of-field mass of nutrients and other constituents in runoff generated on a feedlot due to precipitation. The feedlot algorithm can model daily manure accumulation, various chemical administration patterns, and the periodic scraping of feedlots. The model uses the SCS curve number method to estimate runoff, a non-uniform mixing model to extract constituents from manure, and the manure erosion equation from the APEX model. The daily edge-of-field mass loadings estimated by WINPRZM are then input to the VFSMOD model which estimates the reduction of loadings based on the size of VFS and the resulting concentrations in runoff discharging from the VFS.

**152 The influence of downwind vegetation and distance from application on spray drift deposition to non-target plants**

*D.R. Moore, Intrinsik Ltd; L.S. Ortego, Bayer CropScience / Environmental Toxicology and Risk Assessment; T. Xu, Bayer / Environmental Fate; J. Tang, Bayer; T. Hall, Bayer / Environmental Toxicology and Risk Assessment; A.C. Chapple, Bayer / Environmental Safety; Y. Yang, BayerCropScience / Environmental Fate; J. Hanzas, Stone Environmental, Inc. / Agrochemical Fate and Exposure; B. Brayden, K. Watson, Stone Environmental, Inc.; S.I. Rodney, Intrinsik Corp*

This study is the first in a two-part study designed to determine the distance downwind from treated areas at which non-target plants are no longer significantly affected by applications of an herbicide formulation. The purpose of the initial study was to measure spray drift deposition following application of a "blank" formulation (i.e., no active ingredient) that contained a fluorescent tracer dye for two scenarios: spray drift collectors located downwind on bare ground (worst-case exposure) and collectors located downwind in edge vegetation (typical exposure). The study was conducted from 17-20 October 2017 at an agricultural site in Stilwell, KS in Johnson County using a ground boom sprayer and coarse spray nozzles. Deposition collectors (horizontal and vertical) and plants (navy bean and lettuce) were placed along three transect lines at locations 5, 10, 20, 50, and 100 ft downwind from the edge of the application area. For each exposure scenario, there were four spray swaths that ran perpendicular to the off-field transects. Deposition was always < 1% of applied formulation at 5 feet downwind of the application area and < 0.1% at 50 feet downwind. In addition, the in-vegetation deposition was lower than the bare ground deposition for the more vertical collectors (nylon string, navy bean). However, bare ground and in vegetation deposition were similar for the more horizontal collectors (Mylar card, lettuce). It appears that the presence of vegetation partially blocked lateral transport of the formulation but did not block deposition from above. The second phase of this study is scheduled for October, 2018 and will involve the use of the formulated active ingredient to determine a downwind distance at which the herbicide drift does not significantly affect vegetative growth of lettuce and navy bean placed on bare ground and in edge vegetation.

## Advances in the Toxicological Assessment of PAHs

**153 The use of mass spectrometry to track sources of oil (PAHs) contamination in the marine environment**

*D.M. Pampanin, International Research Institute of Stavanger / University of Stavanger / Environment; M.O. Sydnes, University of Stavanger / Department of Chemistry, Bioscience and Environmental Engineering; K.S. Enerstvedt, University of Stavanger / International Research Institute of Stavanger / Department of Chemistry, Bioscience and Environmental Engineering*

Polycyclic aromatic hydrocarbons (PAHs) are well known contaminants, ubiquitously present in the habitat and spawning areas for Atlantic cod (*Gadus morhua*). The Atlantic cod is a key species and a globally important food source, thus continuous monitoring of PAHs is considered highly valuable to ensure ecosystem sustainability and human food safety. PAH adducts to plasma proteins are used as sensitive biomarkers of PAH exposure in humans and other species, thus the presence of PAH protein adducts in Atlantic cod plasma was investigated to identify PAH protein adduct biomarker candidates of exposure to PAHs. Blood plasma samples were collected from Atlantic cod exposed to single PAHs (i.e. naphthalene, chrysene and their corresponding dihydrodiol metabolites, (-)-(1*R*,2*R*)-1,2-dihydronaphthalene-1,2-diol and (-)-(1*R*,2*R*)-1,2-dihydrochrysene-1,2-diol) and to crude oil. Samples were analyzed by shotgun tandem mass spectrometry (MS) and the resulting MS data were evaluated to screen for proteins susceptible to adduct formation with naphthalene and chrysene and other PAH compounds. Furthermore, a wildcard modification search was performed to obtain additional information regarding potential modifications other than the targeted metabolites. Amino acid adductation sites and metabolites involved in PAH adductation will be presented. Forty-four proteins were found to bind PAHs. The proteins reported with the highest numbers of PAH adducts were alpha-2-macroglobulin-like proteins, apolipoproteins B-100-like proteins and an alpha-2-HS-glycoprotein, which may be the first targets for PAH protein adduct biomarker development in future studies. Furthermore, the wildcard results revealed two highly abundant protein modifications on a hemopexin and alpha-2-macroglobulin protein, and their presence may be of importance for future research. This work provides also the first insight into PAH protein adducts of Atlantic cod plasma, generating valuable knowledge for the development of highly sensitive biomarkers of PAH exposure.

**154 Characterization of PAH contamination using dreissenid mussels in the Great Lakes**

*K. Kimbrough, National Oceanic and Atmospheric Administration; E. Johnson, NOAA / CCMA / National Centers for Coastal Ocean Science; E. Davenport, NOAA; M. Edwards, NOAA National Ocean Service; A.P. Jacob, CSS / National Centers for Coastal Ocean Science*

The National Oceanic and Atmospheric Administration, National Centers for Coastal Ocean Science Mussel Watch Program (MWP) conducts basin-wide monitoring and place-based assessments using dreissenid mussels as bioindicators of chemical contamination in the Laurentian Great Lakes. A multivariate statistical analysis of this long-term combined dataset revealed three distinct PAH concentration patterns by site type: offshore, nearshore and river-harbor, and relationships between total PAH concentration in dreissenid mussel tissue, impervious surface percentages, and PAH relative concentration patterns were explored. To characterize bivalve health, metabolomics, DNA damage, and biomarkers were measured at selected sites and were linked to PAH tissue concentrations to better understand PAH exposure and bioeffects.

**155 Effects of Deepwater Horizon crude oil exposure on the developing teleost kidney**

*F. Bonatesta, University of North Texas / Environmental Science; E. Mager, University of North Texas / Department of Biological Sciences*

Much has been learned with respect to the developmental toxicity of crude oil exposure to teleost fish in the years following the Deepwater Horizon oil spill. Among the key findings are several lines of evidence that specific crude oil constituents, namely polycyclic aromatic hydrocarbons (PAHs), impair the function and proper development of the teleost heart. The resulting reduction in cardiac output is believed to elicit a characteristic suite of downstream effects (e.g., pericardial and yolk sac edema) and likely impairs the proper development of other organs, such as the kidney. While there is some evidence that exposure to individual PAHs impairs development of the early stage kidney (i.e., pronephros), little is known regarding the effects on the pronephros following exposure to complex crude oil mixtures at environmentally relevant concentrations. Furthermore, it is unknown whether early life stage (ELS) effects arising from short-term exposures result in long-term or latent effects on kidney function. To address these knowledge gaps, time-course and dose-response exposures to zebrafish embryos were performed using high energy water-accommodated fractions (HEWAFs) of DHW slick oil. Transcriptional changes in genes with various structural, functional and signaling roles specific to different regions of the developing pronephros (e.g., glomerulus, pronephric tubule and pronephric duct) were assessed by QPCR and whole mount in situ hybridizations. Additionally, the long-term effects of ELS crude oil exposure on kidney function and development was examined using histological assessments and labelling assays to assess nephron function in adults. Results demonstrate transcriptional changes in key genes involved in early kidney development and function and that early stage impairment of normal kidney development might translate into long-term impairment of teleost kidney function. This research was made possible by a grant from The Gulf of Mexico Research Initiative.

**156 The effects of oil-exposure on ammonia and urea excretion in mahi-mahi (*Coryphaena hippurus*) early life stages**

*Y. Wang, University of Miami / RSMAS; J.D. Stieglitz, RSMAS University of Miami / Marine Biology and Ecology; D.D. Benetti, RSMAS University of Miami / Department of Marine Ecosystems and Society; M. Grosell, University of Miami / Marine Biology and Ecology*

The timing and location of the 2010 *Deepwater Horizon* (DWH) incident within the Gulf of Mexico coincided with the spawning of many commercially and ecologically important fish species, such as mahi-mahi. Early life staged mahi exposed to environmentally-relevant crude oil concentrations have displayed increased oxygen consumption suggesting an increased metabolic rate which is mainly fueled by protein catabolism from the yolk sac. In teleosts, protein is usually catabolized into ammonia or urea. Recent studies by our lab revealed that, similar to other teleosts, mahi avoid the toxic build-up of ammonia by being largely ureotelic during the embryonic stage and gradually switch to being ammoniotelic for less ATP cost at the time of hatch (42-48 hpf). The excretion process happens mostly at the gills, where Rh protein family (Rhag, Rhbg, Rhcg1 and Rhcg2) works as ammonia transporters and UT works as urea transporter. In this study, mahi embryos and larvae were exposed to 2%, 4% and 6 % HEWAF (6.4, 14.2, 20.7 µg $l^{-1}\sum$50 PAH) to investigate the impacts of crude oil on ammonia and urea excretion by examining gene expression changes of related transporters over the initial 102 hpf of life. Crude oil was found to significantly increase mRNA levels of ammonia transporters in embryos until hatch but not urea transporters. Each ammonia transporter's response to crude oil was differently among development which suggests varied function of the transporters. The upregulated mRNA levels of transporters support observations of increased metabolic demand fueled by protein metabolism, especially during hatch when any physiological change could impact larvae survival. Our results contribute to understanding the underlying mechanism of toxicity from crude oil in early life staged pelagic fish. Efforts to measure the ammonia and urea excretion rate after oil-exposure are currently ongoing. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520.

**157 Is the stress response of Gulf toadfish affected during a one-week DWH oil exposure and what is the potential for recovery?**

*M. Cartolano, M.M. Alloy, M. McDonald, RSMAS University of Miami / Marine Biology and Ecology*

The polycyclic aromatic hydrocarbons (PAHs) released in the Deepwater Horizon (*DWH*) oil spill have been found to impair the glucocorticoid stress response of vertebrate species found in the Gulf of Mexico (GoM). Specifically, reduced plasma cortisol levels measured in marine mammals found in areas contaminated by *DWH* oil and in teleosts exposed experimentally suggest a reduced ability to properly respond to natural environmental stressors. The mechanisms for this remain unclear; inhibition in cortisol secretion may be due to pituitary fatigue through over-stimulation of the hypothalamic-pituitary-interrenal (HPI) axis or could be via an inhibition of cortisol biosynthesis through interactions of PAHs and the aryl hydrocarbon receptor (AhR). Gulf toadfish, *Opsanus beta*, a GoM resident, will serve as a model species to understand the effects of *DWH* PAHs on the HPI axis and the potential for recovery. Using a flow-through system, toadfish were continuously exposed to control conditions or three environmentally relevant concentrations of PAHs from *DWH* high energy water accommodated fraction (HEWAF; ∑PAH = 0 – 10 µg?$L^{-1}$) for 0, 4 h, 8 h, 24 h, 3 days, 7 days followed by recovery for 7 days with sampling occurring at the same time periods. At these exposure and recovery time points, corticotropin releasing factor (CRF) mRNA expression in the hypothalamus will be quantified using qPCR to determine if PAHs are perceived as a stressor, thus stimulating the HPI axis. Circulating adrenocorticotropic hormone (ACTH) that is released from the pituitary will be quantified in the blood plasma to determine if oil exposure has the potential for pituitary fatigue. Additionally, mRNA expression of the interrenal melanocortin 2 receptor (MC2R), the steroidogenic enzymes StAR, cytochrome P450 side chain cleavage (P450scc), and 11β-hydroxylase, and plasma cortisol concentrations will be measured to determine if PAHs may have the potential to affect the responsiveness to ACTH and subsequent cortisol production and secretion. Cytochrome P4501A1 (CYP1A) mRNA expression will also be measured throughout HPI axis tissues to measure potential involvement of the AhR. Temporal changes in the components of the HPI axis in response to different PAH concentrations and exposure and recovery lengths will allow us to better understand if PAHs are overstimulating the HPI axis or impairing the HPI axis through the AhR pathway and will serve as a foundation for future chronic exposures.

**158 Associations between microscopic hepatic changes and PAH accumulation in wild-caught Gulf of Mexico Golden tilefish**

*S. Snyder, E. Pulster, University of South Florida / College of Marine Science; S.B. Fogelson, Fishhead Labs LLC; S.A. Murawski, University of South Florida*

The Center for Integrated Modeling and Analysis of Gulf Ecosystems (C-IMAGE) completed a series of Gulf-wide cruises, 2012-2017, to study the prevalence of fish disease and polycyclic aromatic hydrocarbon (PAH) contamination in Gulf of Mexico demersal fishes. Golden tilefish (*Lopholatilus chamaeleonticeps*) were chosen as a target species due to their strong association with sediments, relatively high levels of a biomarker of PAH exposure (x = 280 ug/g biliary naphthalene metabolites) and accumulation of PAHs in liver tissue (x = 2700 ng/g w/w total PAH). Fish were collected via demersal longlining from stations (n = 23) on the United States and Mexican continental shelf at depths typically 200-450 meters. A variety of tissues were sampled for contaminant analyses and pathology, including liver and bile presented herein. Histological evaluations of 239 livers were performed by a board-certified veterinary pathologist at Fishhead Labs LLC. Biliary PAH metabolites were analyzed semi-quantitatively using standard high performance liquid chromatography with fluorescence detection (HPLC-F) methods. PAHs and alkylated homologs were extracted from liver tissue using QuEChERS Enhanced Matrix Removal (EMR) and quantified via gas chromatography tandem mass spectrometry (GC-MS/MS). Preliminary results from individuals (n = 163) collected in the north-central Gulf around the De Soto Canyon show widespread occurrence of hepatic changes (99% of fish evaluated), with the most frequent being glycogen-type vacuolar change (76%), pigmented macrophage aggregates (61%) and biliary fibrosis and duplication (49%). Occurrence of neoplasms was rare (n=1; hepatocellular adenoma), however, approximately 10% of individuals examined exhibited foci of cellular alteration (FCA), often considered "preneoplastic" lesions. Preliminary analysis suggests associations between increased occurrence of atrophy, FCA and biliary fibrosis with biomarkers of PAH exposure, as well as associations between increased occurrence of glycogen-type vacuolar change, FCA and biliary fibrosis with PAH accumulation in hepatic tissue. Further analysis of spatial and temporal trends in hepatic changes and PAH contamination is underway. This study is the first to evaluate the effects of chronic anthropogenic pollution on Gulf of Mexico Golden tilefish health.

**159 Photo-induced toxicity of polycyclic aromatic hydrocarbons and relationship to body burden in two amphibian species**

*Z. Currie, University of Saskatchewan / Toxicology Centre; S. Siciliano, University of Saskatchewan / Department of Soil Science; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre*

Certain polycyclic aromatic hydrocarbons (PAHs) exhibit photo-induced toxicity with ecologically relevant intensities of ultraviolet (UV) light, resulting in increased mortality and developmental effects in aquatic organisms. Photo-induced toxicity of PAHs is dependent on many factors including internal PAH concentration, which can vary across species and dependent on toxicokinetics. Early life-stages of amphibians may be particularly susceptible to PAH photo-induced toxicity as they can accumulate PAHs and often develop in shallow ponds where they are exposed to UV light. The objective of this research was to assess and compare that

photo-induced toxicity in two amphibian species following exposure to PAHs and determine whether relative differences in sensitivity between species is related to accumulated levels of specific PAHs. *Lithobates sylvaticus* (wood frog) and *Xenopus laevis* (African clawed frog) early life stage tadpoles were exposed to three individual PAHs (benzo(a)pyrene, anthracene, and naphthalene). Tadpoles were allowed to accumulate chemicals over 8 h at which time samples were taken for body burden analysis. Tadpoles were then transferred to clean water under UV exposure for 12 h and then grown out without UV or chemical exposure until the end of the 96 h toxicity test. *Xenopus* and wood frog tadpoles exposed to anthracene or benzo(a)pyrene followed by UV light had higher mortality when compared to either PAH alone. *Xenopus* had decreased length and increased deformities when exposed to UV light alone regardless of chemical treatment. Wood frogs exposed to 2 and 20 ug L-1 anthracene, and 100 ug L-1 benzo(a)pyrene had a significantly higher body burden compared to *Xenopus* exposed to the same concentrations. The LC50 value for *Xenopus* exposed to anthracene and UV light was 5 ug L-1, while the LC50 value for wood frogs exposed to anthracene and UV light was 124 ug L-1 leading us to conclude that for anthracene, toxicity thresholds based on *Xenopus* would be protective for the wood frog. The LC50 values for benzo(a)pyrene and UV light were more comparable between species with 45 ug L-1 for *Xenopus* and 17 ug L-1 for wood frogs. Overall, this research demonstrates that photo-induced toxicity is an important consideration in the hazard assessment of PAHs, provides new data on the acute phototoxic effects of PAHs in two amphibian species, and indicates that species differences in response are not driven by differences in PAH uptake.

**160 Does predation risk increase with crude oil exposure?**

*A. Khursigara, J.L. Johansen, L.E. Rowsey, University of Texas Marine Science Institute; A. Esbaugh, University of Texas Marine Science Institute / Department of Marine Science*

As a pervasive toxicant, crude oil is a major ecological concern worldwide. The suite of cardiotoxic injuries sustained by oil exposure, primarily driven by three-ring polycyclic aromatic hydrocarbons, has been well described in fish species. This impaired cardiac function has been shown to reduce aerobic scope and swim performance in a number of species. Recently there has been evidence to suggest that fish also suffer neurological and cognitive function impairment following oil exposure. However, little is known about the ecological implications of these sub-lethal injuries, including predation risk. This study investigated the possible impacts of oil exposure on predation risk in small juvenile red drum, *Scianeops ocellatus*. A mesocosm-style approached was used immediately following an acute exposure. We first examined routine habitat utilization behavior after which common predators were introduced and time to mortality was monitored. Using an environmentally realistic oil concentration, swim speed ($U_{crit}$) was used as a marker of impaired physiological performance. Results suggest that while there was no difference in aerobic scope, oil exposed fish had a significantly lower $U_{crit}$ than controls. In the mesocosm-style study, oil exposed groups were more likely to utilize open sandy bottoms than control fish who preferred either seagrass areas or the wall. Consequently, the time to 50% mortality by predation was also significantly lower in oil exposed fish. These findings demonstrate that sub-lethal oil exposure can have important downstream ecological consequences.

## Water: Bringing Science and Engineering Together to Address Impacts of Climate Change on Water Supply and Water Quality

**161 Preparing for Droughts in a Changing Climate**

*E. Hanak, PPIC Water Policy Center*

California already has the most variable precipitation in the continental United States, requiring the state to be prepared to weather both multi-year droughts and severe episodic floods. A suite of studies conducted by the PPIC Water Policy Center on lessons from the 2012–16 drought—the hottest and most severe in modern times—provides insights into drought vulnerabilities and priorities across four sectors—cities, farms, rural communities, and freshwater ecosystems. We found that cities were best prepared, that agriculture was able to adapt through judicious demand management and significant extra groundwater pumping, and that both rural community drinking water systems and freshwater ecosystems were least prepared, and most vulnerable, to extreme drought. As the climate continues to change, several factors will require the state's water policies and management strategies to further adapt to protect the economy and vulnerable communities and ecosystems. Models project continued warming of air and water temperatures, reduced mountain snowpack (now an important source of seasonal water storage), shorter wet seasons, and more intense precipitation variability—with wetter wet years and drier dry years (Ullrich et al. in review, Swain et al. 2018). These changes will put additional pressures on the water system—increasing the water demands for farmland and landscape irrigation, and making it more challenging to balance the competing uses of aboveground reservoirs for urban and farm water supply, cold water for fish, and flood protection. This presentation will describe recommendations on four overarching actions needed to build resilience and reduce vulnerability to droughts of the future: developing more robust drought plans, upgrading the water grid—including above and below-ground storage and to accommodate changing patterns of runoff, updating water allocation rules to facilitate flexible responses to scarcity, and finding the money to address funding gaps in vulnerable sectors. Some of these reforms can be accomplished by building on adaptation work already underway, and others will require a change in course. Successful implementation of the state's Sustainable Groundwater Management Act, adopted in 2014 at the height of the last drought, will be central to success.

**162 Evaluating consequences of POTW effluent in US streams during low flow events**

*J. Rice, University of North Carolina at Charlotte*

Each day over 14,000 publicly owned treatment plants release 87 million $m^3$ of treated wastewater into the nation's freshwater supply, making publicly owned treatment works (POTW) discharges one of the highest inputs of anthropogenic loadings to natural waters. Treated wastewater plays many roles in the U.S.'s aquatic environment and surface water portfolio. Persistent wastewater pollutants potentially pose environmental and human health risks, however treated wastewater can also serve as a primary source of streamflow which in turn can be critical in maintaining stream ecosystems. In this study, a recently-developed national-scale model (DRINCS) was applied to estimate POTW contribution to the loading of contaminants of emerging concern within U.S. surface waters during low streamflow events. Our results indicate streams are vulnerable to endocrine disrupting compounds (EDCs) during periods of low streamflow. And the dependence of contaminant concentrations on streamflow conditions highlights the role that streamflow conditions can play when analyzing surface water samples for EDCs and other wastewater contaminants. This work demonstrates how modeling efforts can be a good accompaniment to environmental sampling, by identifying stream locations where contaminants are expected to be high, signaling where further chemical analysis is warranted.

**163 Assessment of the use of dry wells to infiltrate urban runoff to recharge the aquifer: The Elk Grove Dry Well Study**

*B.S. Washburn, OEHHA / Cal EPA / Ecotoxicology Program; E.C. Edwards, Lawrence Livermore National Laboratory; C. Bowles, cbec eco-engineering; G. Fogg, T. Harter, UC Davis / Land, Air, and Water Resources; B. Lock, OEHHA / Cal EPA / Air, Community, and Environmental Research Branch; C. Nelson, Unico Engineering*

Water reuse is a strategy for optimizing water resources in the face of the changing hydrology associated with climate change in California and elsewhere. One approach involves using dry wells to infiltrate urban stormwater (SW) to recharge the aquifer. However, concerns exist regarding the protection of groundwater quality and drinking water. The Elk Grove Dry Well Study in vestigated this risk by constructing two pilot dry well with pretreatment and a network of monitoring wells, one in a residential neighborhood and a second in a large parking lot for the bus fleet in Elk Grove. Stormwater runoff was collected during 5 rain events and groundwater collected shortly thereafter. Over 200 contaminants were analyzed. Vadose zone modeling was performed to estimate the fate and transport of contaminants found in SW as well as emerging pollutants over a 1000 year timeframe. Data was analyzed using non-parametric statistics, comparing SW before and after pretreatment, in the vadose zone, and in upgradient and downgradient water table wells. Contaminants such as aluminum and bifenthrin that were detected at elevated concentrations in SW were present in low concentrations or not found in groundwater. In many cases, the concentrations of pollutants were no different in upgradient and downgradient wells, suggesting that dry wells were not the source of the contaminants. In contrast, pollutants present at elevated concentration in groundwater, such as chromium or arsenic, were very low or not detected SW. Results of vadose zone modeling suggested that most pollutants would not be quantifiable within the modeling timeframe. Exceptions were two water soluble pesticides, imidacloprid and fipronil. These pesticides are weakly sequestered in the vadose zone and unlikely to be effectively contained by pretreatment. However, their concentrations at the water table after 500 years were 2-fold (fipronil) and 400-fold (imidacloprid) below the health protective concentrations, therefore would pose little risk to human health. Lastly, an extensive review of the literature found little evidence to suggest that the use of dry wells led to a systematic contamination of groundwater. We concluded that dry wells can be safely used to recharge the aquifer if pretreatment and other reasonable safety measures, related to siting and management, are employed.

### 164 Climate change impacts on agriculture in California

*T. Pathak, UC Merced*

California produces more than 400 types of commodities and is a global leader in production of various fruit and nut crops as well as vegetables. With 77,500 farms and 3.8 million ha of irrigated cropland, California generates an overall agricultural production value of $50.5 billion. Despite being the world leader in agricultural production, California agriculture is vulnerable to current and future impacts of climate change. We carried out a detailed review of trends in temperature, precipitations, snowpack, and extreme events including drought and heat waves and consequent impacts on California agriculture. The range of studies on trends and impacts of climate change on California agriculture justifies the importance of enhancing the adaptive capacity of agriculture to climate change impacts, increased research effort to agricultural adaptation to water shortages, and effective stakeholder engagements.

### 165 Nitrate: A Global Water Challenge & Critical Element in Food, Water, Energy Systems

*P. Westerhoff, Arizona State University / School of Sustainable Engineering and The Built Environment*

Nitrogen fertilizer is essential to high productivity agriculture (the Green Revolution); for at least 1/3 of the world's population, N-based fertilizer is the difference between malnutrition and an adequate diet. Industrial production of ammonia ($NH_3$) from di-nitrogen ($N_2$) in the atmosphere via the H-B process consumes 1-2% of the world's annual energy. Loss of N from the food system is a serious environmental problem that leads to atmospheric pollution, dead zones, and eutrophication of freshwater and marine ecosystems. Overall, human use of N-based fertilizers in food production has altered the natural N cascade (i.e., sequential transfer of N between ecosystems). One consequence has been the accumulation of nitrate in aquifers beneath recent and current agricultural areas, which is now needed as a potable water supply. This presentation will describe emerging technologies suitable for removing, rather than just separating, nitrate from drinking water. The focus will be on non-biological treatment processes, because these offer tremendous flexibility and ease of operation.

### 166 A Tiered Framework to Evaluating Risks of Emerging Contaminants from Water Reuse in Agroecosystems

*J. Gan, University of California, Riverside / Environmental Science; Q. Fu, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Department of Environmental Chemistry; C. Sun, UC Riverside / Environmental Science; S. Dudley, UC Riverside / Environmental Toxicology*

Irrigation with treated wastewater and application of biosolids or animal waste introduce numerous contaminants of emerging concern (CECs) into agroecosystems. Accumulation of CECs in food produce constitutes a potential food safety and human health risk. However, a comprehensive risk assessment and management of CECs in food-production systems, i.e., agroecosystems, is constrained by multiple factors, the utmost of which is the enormous number and diverse characteristics of CECs. Here we summarize the current knowledge on accumulation of CECs in plants including vegetables from irrigation of treated wastewater under hydroponic and field conditions. We then delineate processes contributing to the ultimate accumulation of CECs in edible tissues in the soil-plant continuum. We further outline a tiered framework as the path forward to prioritize CECs that may have a high risk for accumulation in food produce. This tiered approach is valuable as it helps us focus our research efforts only on the priority CECs and thus maximizes the use of our limited research resources to tackle this urgent issue.

### 167 Exploring the Interdependencies Between Water, Energy and Climate

*V. Tidwell, Sandia National Laboratories; N. Voisin, Battelle Pacific Northwest Laboratories; J. Macknick, National Renewable Energy Laboratory; E. Yang, Lehigh University*

Energy production withdraws more water than any other sector in the U.S. Water is used to cool thermoelectric power plants, produce hydropower, process fuels and extract energy minerals. Water is also highly dependent on energy for pumping, treatment and distribution. Climate challenges these interdependencies by changing the timing and intensities of stream flows, increasing water and energy demands, changing water quality and encouraging use of non-potable waters requiring increased treatment and transport. Planning and management of this complex interplay is further complicated by uncertainties in future climate, resource demand, technology and policy. In efforts to explore the sustainability and resilience of these interdependent systems an integrated mulit-sector, multi-scale modeling effort is being pursued. Multi-sectoral modeling involves the linking of the physical system (Earth System Models and surface hydrology) with the engineered (reservoir routing and electric dispatch) and human systems (Agent Based Modeling). These coupled systems of models are reproduced at the local, water basin and regional scales. Specifically, comparative analyses link case studies of the San Juan River (northwestern New Mexico), Colorado River Basin and the Western U.S. Numerical experiments explore how system vulnerabilities evolve and how their unique pathways differ not only by the impact metric considered but also according to the region and scale of analysis. Recently, studies have been initiated to consider the efficacy of competing response actions in terms of alternative water supplies, advanced technology, policy and human behavior. *This research was supported by the U.S. Department of Energy, Office of Science, as part of research in Multi-Sector Dynamics, Earth and Environmental System Modeling Program. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA-0003525.*

**168 Perspectives from California Water Resources Control Board Member Tam Doduc**

*T. Doduc, California Water Resources Control Board / Board Member*

The California Water Resources Control Board and the Regional Water Quality Control Boards are key parts of the California water system. I will discuss some of our current efforts and thoughts. Integrated efforts on water supplies and management. The Boards support strategies to increase resilience, such as water conservation and efficiency, investments in local water supply development, water recycling, storm water capture and use, increased groundwater recharge, surface storage, and conjunctive use water management, watershed and meadow restoration to enhance natural "above the dam" storage, and groundwater replenishment and sustainable management. The human right to water. For millions of Californians, drinking water costs are high. Also, many residents do not have access to clean and reliable drinking water. Climate change could cause additional challenges to water quality, water supplies, and drinking water and wastewater infrastructure. Disadvantaged communities that already have problems in securing safe water and sanitation will likely have difficulty adapting. The Boards' efforts include the Low-Income Rate Assistance Program, programs of the Office of Sustainable Water Solutions, support for additional consolidation of small drinking water systems that serve disadvantaged communities, and funding efforts. Sustainable groundwater. The Sustainable Groundwater Management Act (2014) will be an important framework for water-related climate adaptation. Moving to sustainability is a long-term effort: groundwater sustainability agencies are required to consider a 50-year "planning and implementation horizon." The Boards plan to facilitate good governance and good outcomes in a range of ways. Water rights. California's approach to water rights is unique relative to other western states, in that the state combines a traditional riparian system (proximity to a water course) with an appropriative (first-in-time, first-in-right) system. This dual system has led to challenges in water rights administration and requires early planning and scenario analysis for water users to obtain new water right appropriations. At present, new appropriations do not consider future climate change scenarios or what climate change will mean for future water availability. Wrestling with the question of climate change and future water availability will require concerted and long-term engagement with the public and the Legislature.

## One Health in Action – Tangible Applications for Problem Solving and Coalition Building

**169 Application of multidisciplinary sciences within USGS toward environmental health goals**

*P. Bright, US Geological Survey / Environmental Health; D.E. Tillitt, US Geological Survey / Columbia Environmental Research Center*

One Health recognizes that there are direct linkages between the environment and the health of humans and other organisms. A key aspect of One Health is understanding how earth processes, environmental factors and human activities interact to influence exposures to microbial, inorganic, and organic contaminants from geologic, anthropogenic, and disaster sources. Moreover, it is critical to understand the health impacts resulting from these exposures. There are many well-known examples of how exposures to contaminants can lead to disease. Many vector-borne and zoonotic diseases are also known to be influenced by environmental conditions, and measures to mitigate disease exposures (such as pesticide usage) can, in turn, have potential health implications. Yet there are still significant gaps in our scientific knowledge; filling these gaps requires truly transdisciplinary collaborations involving a broad spectrum of disciplines (including but not limited to earth, environmental, biological, ecological, social, engineering, and health sciences). This presentation will highlight current US Geological Survey science activities focused on fish and wildlife toxicology research with potential human health implications, collaboration between human health and wildlife researchers, the impact of ecosystem services on health, and the health impacts of environmental disasters.

**170 Toxicological effects of anabaenopeptins and cyanopeptolins to a model organism the nematode C. elegans**

*K.A. Lenz, UWM-ZSPH / Environmental Health Sciences; T.R. Miller, H. Ma, University of Wisconsin Milwaukee*

Cyanobacterial blooms represent a significant risk to environmental, ecological, and human health due to their production of toxic and/or bioactive secondary metabolites, or cyanopeptides. Anabaenopeptins and cyanopeptolins are cyanopeptides that have been increasingly detected in drinking water, food sources, and medicinal agents and supplements at concentrations exceeding toxicity levels for other cyanopeptides (such as microcystins). Yet, their potential environmental and human health implications are not well understood. Here we assessed the toxicological effects of three anabaenopeptins (AP-A, AP-B, and AP-F) and three cyanopeptolins (CYP-1007, CYP-1020, and CYP-1041) to a model organism the nematode *Caenorhabditis elegans* (*C. elegans*). Examined toxicity endpoints included reproduction, hatching time, growth rate, lifespan, and age-related vulval integrity. Microcystin RR (MC-RR) and microginin 690 were also included in the study for comparisons. Eggs or young adult worms were exposed to an environmentally relevant concentration of these cyanopeptides (10 µg/L) and observed for potential toxicological effects through the life course of the worms. APs showed the greatest toxicity among all cyanopeptides tested, indicated by reduced reproduction, delayed hatching, reduced growth rate, shortened lifespan, and severe vulval integrity defects. The three APs (10 µg/L) decreased worm reproduction, indicated by the number of progeny per worm, by 23%-34% compared to the control. APs also induced an average of 1.6 hr delay in hatching, reduced the average growth rate by 12.3%-15.7% after 24hrs, and shortened the lifespan by 5 days (corresponding to a 30% reduction in lifespan). The most remarkable impact of these APs was the Avid (age-related vulval integrity defect) phenotype, where more than 95% of exposed worms developed an Avid phenotype, compared to a less than 10% incidence in control worms. Cyanopeptolins (CYPs) displayed similar toxicity as MC-RR, and Microginin 690 was the least toxic. These findings suggest that APs and CYPs may pose significant health risks to aquatic organisms, and potentially human health. Overall this study suggests more toxicological studies of these cyanopeptides using different species across different trophic levels are needed to gain a thorough understanding of their potential impact on ecological systems and human health.

**171 Concentrations and risks of metal contamination from lead shot in a Hawaiian green sea turtle (*Chelonia mydas*) foraging aggregation and their habitat**

*K. Shaw, Texas Tech University / Environmental Toxicology; G. Balazs, T. Jones, National Oceanic and Atmospheric Administration / Pacific Islands Fisheries Science Center; H.W. Lynch, The Nature Conservancy of Hawaii; D. Klein, Texas Tech University / Department of Environmental Toxicology; J.M. Lynch, National Institute of Standards and Technology / Chemical Sciences Division*

The Kaimalino neighborhood in Kailua Bay, Hawaii, located on windward Oahu, was once the home of the Honolulu Skeet Club. During the 40 years the skeet club was active, lead (Pb) shot was used resulting in an accumulation of these pellets on and near the coastline. The pellets slowly degrade and release Pb, arsenic (As) antimony (Sb) and tin (Sn) and put organisms living, breeding, and foraging in this area at risk of heavy metal accumulation and toxicity. Signs at the public access point currently warn that Pb and As found in pellets along the shoreline may be harmful to children if swallowed. The Honolulu Skeet Club is listed as an active superfund site by the Environmental Protection Agency, but is not on the national priorities list. One species found in Kailua Bay is the threatened green sea turtle (*Chelonia mydas*). Green sea turtles studied since 2000 along the shoreline of Kaimalino neighborhood at the mouth of the Kawainui Marsh are highly resident, with 75% of turtles re-captured during sampling events spanning three years, 2011-2013. This high site fidelity allows sea turtles to serve as bioindicators of contaminants in Kailua Bay. In a preliminary study, the maximum blood lead concentration in Kailua Bay turtles was 140 ng/g. This exceeds the Center for Disease Control children blood Pb reference level of concern of 40 ng/g by more than three times. An additional 33 turtles have been sampled for this study. Ten of these turtles were sampled twice, providing a temporal history of blood and scute Pb, As, Sb, and Sn concentrations, while the remaining 23 turtles were sampled once. Some of the turtles sampled are new recruits from the pelagic habitat to the bay with a straight carapace length (SCL) of approximately 40 to 45 cm. Larger turtles that have been caught over multiple years are likely residents of the bay, and potentially exposed to the Pb shot for multiple years. Sediment, algae, water, and lead shot samples taken from Kailua Bay will allow us to trace the metals through the ecosystem and provide additional data for possible human exposure.

### 172 Reciprocating Relationships to Wellness

*T. Godfery, Avicennia Education / School of Undergraduate Studies; H. Hireme, Te Whare Wananga O Awanuiarangi / School of Undergraduate Studies*

In his essay titled The Land Ethic, Aldo Leopold (1949) states "*There is as yet no ethic dealing with man's relation to land and to the animals and plants which grow upon it. Land, like Odysseus' slave-girls, is still property. The land-relation is still strictly economic, entailing privileges but not obligations.*" Whilst this statement remains true throughout much of the world, conversely, the concept of land as property is disturbing to many indigenous communities. An advanced ethic of environmental care has developed over time, with indigenous peoples amongst continuing practitioners of this ethic. An ethic premised upon interconnectedness and interdependence, which includes relationships of reciprocity and respect. Notwithstanding the integrative nature of the One Health model, caution is however necessary when including elements based upon indigenous relationships. Practitioners must ensure these elements maintain integrity, and are not subsumed by scientific or technical components. This paper discusses the value of reciprocal and respectful relationships with environment, proposing such relationships are vital to achieving wellness. Discussion also highlights potential contributions to the One Health Model.

### 173 Examining the relationship between chemical/non-chemical stressors and inherent characteristics to explain disparities in children's mental health

*F. Nilsen, USEPA / National Exposure Research Lab; N.S. Tulve, US Environmental Protection Agency / Office of Research and Development / National Exposure Research Laboratory*

Children may be more vulnerable to the combined interactions of chemical and non-chemical stressors from their built, natural, and social environments when compared to adults. Up to 20% of children are diagnosed with a mental illness annually in the United States with a large number not receiving adequate treatment. This project aims to elucidate the links between chemical and non-chemical stressors and inherent characteristics on children's mental health outcomes using our multifactorial conceptual framework. Serotonin is one of the most important neurotransmitters related to mental health. Monoamine oxidase A (MAOA) aids in serotonin uptake and has two genotypes that affect its enzymatic activity (low; L, and high; H). MAOA-L carriers are more frequently diagnosed with behavior and emotional disorders. When children are exposed to cigarette smoke, bisphenol A (BPA), or organophosphate pesticides, MAOA activity is inhibited. Non-chemical stressors, such as traumatic childhood experiences, ethnicity, and lifestyle factors, complicate the relationship between genotype and chemical exposure. But, the co-occurrence among outcomes between chemical exposures, genotype, and non-chemical stressors with MAOA-L suggest that mental illness in children may be caused by multiple interacting factors. The interacting factors described here are being assessed by a state-of-the-science review to clarify the relationship and discrepancies observed. Preliminary results show that exposed animals acquire behaviors characterized by MAOA-L. In humans, adult non-chemical stressor exposure is correlated to many MAOA-L associated mental health outcomes, and MAOA-L children experiencing trauma typically develop at least one mental disorder. Chemical exposure is not considered in most epidemiological analyses, but may be a contributing factor. Population genetics also play a role in behavioral outcomes, but results often contradict what is established for MAOA-L, with epigenetic changes adding another layer of complexity. If a relationship is observed across all factors, a meta-analysis using mental health, traumatic experience, and genetic data will be conducted to better understand the causes of mental illness in children. An improved understanding of inherent vulnerability and the onset of mental illness may provide better intervention and treatment options to children in need.

### 174 A Health and Ecological Systems Framework for Vector-Borne Diseases in Puerto Rico

*W.S. Fisher, US Environmental Protection Agency / Office of Research and Development / National Health and Environmental Effects Research Laboratory; R. de Jesus Crespo, US Environmental Protection Agency / Gulf Ecology Division / National Health and Environmental Effects Research Laboratory / Office of Research and Development; S.H. Yee, U. S. EPA / Gulf Ecology Division / National Health and Environmental Effects Research Laboratory / Office of Research and Development*

Environmental, social and economic factors can influence public health, but the interactions can be difficult to understand and anticipate. A systems context, that is, a conceptual approach that simultaneously considers environmental, social and economic factors, is essential. Previously in the One Health session, we described a systems framework originating from an environmental context (DPSIR—Driving force, Pressure, State, Impact and Response) that was adapted to include social and economic aspects of human activity and behavior. The resulting EcoHealth DPSIR was illustrated using vulnerability and effects of asthma. The concept is further illustrated by examination of recent research in the San Juan metropolitan area of Puerto Rico in relation to vector-borne (mosquito) Zika and dengue diseases. Two studies demonstrated correlation of environmental factors, such as wetland area, nutrient enrichment, rainfall and flooding with the capacity of mosquito populations to carry virus and subsequent disease incidence in humans. Socio-economic factors, such as income level, moderated the influence of environmental factors on disease incidence in humans. The resulting relationships emphasize the importance of factors like equity, governance and personal choices in public health; and the consequent impacts of disease on human well-being and economic production.

### 175 One Health approach to addressing a mysterious kidney disease

*R. Babich, University of Maine; A. Massarsky, Duke University / Nicholas School of the Environment; Y. Sugano, Harvard University; K. Wanigasuriya, P. Manage, University of Sri Jayewardnepura; R.T. Di Giulio, Duke University / Nicholas School of the Environment; I. Drummond, Harvard University; N. Jayasundara, Universiy of Maine / School of Marine Sciences*

A mysterious chronic kidney disease (termed as chronic kidney disease of unknown etiology – CKDu) has emerged across certain farming communities across the world, including in South Asia. Notably, this disease is a major epidemic in rural agricultural communities in Andhra Pradesh, India and in several parts of Sri Lanka. In affected communities in Sri Lanka, 20% of the adult population is diagnosed with the disease. The primary obstacle to mitigating CKDu is the unknown etiology of this condition. Exposure to environmental contaminants (e.g., heavy metals and pesticides) through ingestion is thought to contribute to CKDu. However, a specific role for individual chemicals has been repeatedly tested without compelling positive results. Alternatively, synergistic and interactive toxic effects of chemical mixtures are hypothesized to cause CKDu. Nonetheless, despite being much more environmentally realistic, evaluating the role of chemical mixtures in CKDu as well as in other chronic diseases remains a major challenge. Here, to gain insights into adverse health effects of exposure to chemical mixtures in regions affected by CKDu, we integrated laboratory exposure studies and sentinel species analyses. For laboratory studies, we used zebrafish *Danio rerio* embryos to evaluate toxicity of chemical mixtures derived from lakes and drinking-water wells from CKDu regions. We examined exposure effects on survival rates, teratogenicity, kidney specific oxidative stress, kidney development, mitochondrial function, and kidney specific gene expression changes. To complement our laboratory studies, we are taking a One Health approach to examine teleost kidney health in fish inhabiting lakes from affected regions. Chemical analyses of mixtures derived from these regions showed that cadmium, arsenic, and lead are present in these mixtures, but at levels well below current safety thresholds. Despite low levels of these chemicals, toxicity studies indicate that chemical mixtures derived from lakes and wells from CKDu affected regions are toxic to mitochondria and induce kidney specific oxidative stress as well as gene expression changes. Importantly, including sentinel species into our studies is providing a framework for integrating a One Health approach in evaluating and predicting adverse health effects of long-term exposure to chemical mixtures.

**176 Translational Science Research and One Health**

*C. Baghdikian, US Environmental Protection Agency / Office of Research and Development / National Health and Environmental Effects Research Laboratory*

There are several complex or “wicked” problems related to air, water, and soil that impact ecosystems and communities both domestically and abroad. Many of these problems are aligned with USEPA’s mission to protect human health and the environment. Addressing these wicked environmental problems requires interdisciplinary approaches that engage multiple stakeholders to fully characterize the nature of the problems and their potential solutions. To improve research planning and direct applicability of research to stakeholder needs, ORD recently launched a Translational Science initiative. Translational science is the study of translational research – how to produce and deliver science that directly informs decisions or actions, e.g. how to move from science to solutions. Translational research approaches emphasize stakeholder engagement throughout the entire research process, starting with problem formulation and informing all elements of research planning, implementation, dissemination, and evaluation. This initiative consists of a three-pronged approach: 1) apply principles of translational research broadly across ORD’s six research programs; 2) conduct two translational science pilots to advance the science of how we do translational research; and, 3) prepare case studies of translational research approaches in ORD to begin to extract successful methods. This session will describe some of the processes and findings of each of these activities as they relate to the interdisciplinary, multi-stakeholder nature of the problems that face the One Health community at SETAC.

# Cradle to Grave Impacts of Nanotechnology

### 177 Comparative Life-cycle Analysis of Nitrate and Perchlorate Technologies for Microbial Sulfate Reduction Inhibition in Offshore Oil Fields

*B. Neupane, Energy Biosciences Institute / University of California, Berkeley; C.D. Scown, Lawrence Berkeley National Laboratory / Energy Analysis & Environmental Impacts*

Hydrogen sulfide ($H_2S$) generation by sulfate-reducing microorganisms (SRM) presents human health, environmental, and economic risks in the offshore oil production industry. Corrosion due to hydrogen sulfide ($H_2S$) generation is the leading cause of oil industry infrastructure failure with high economic consequences, estimated to range billions of dollars per year. This study compares the life cycle environmental performance of existing nitrate and proposed perchlorate-based technologies to prevent $H_2S$ formation and evaluates environmental impacts of oil leaks and spills due to corrosion damages at offshore oil wells. We developed a detailed comparative life-cycle inventory to examine the environmental impacts, including GHG emissions and ecotoxicity impacts of sodium perchlorate and calcium nitrate production, and of their subsequent use in an offshore oil field to prevent hydrogen sulfide ($H_2S$) generation. We also report the environmental damages in offshore oilfield due to $H_2S$ generation and potential benefits of sodium perchlorate treatment in preventing such impacts. We used the real field data (i.e., oil production rate, $H_2S$ generation, nitrate injection rate, etc.) based on an offshore oil field in Europe. Using the best available data, we found that a sodium perchlorate treatment strategy can offer substantial environmental and economic savings relative to calcium nitrate at eliminating $H_2S$ corrosion-related oil well shutdowns. Our results suggest that, although both the technologies have comparable GHG emissions across the supply chain, other impact categories such as acidification and toxicity impacts are improved with sodium perchlorate treatment. Given the uncertainty with the several process parameters, detailed sensitivity analysis is conducted to better understand the potential impact on the environment across the supply chain.

### 178 Modeling Spatial Dimensions of Life Cycle Nanomaterial Emissions

*E. Moore, C.W. Babbitt, Rochester Institute of Technology / Golisano Institute for Sustainability; B. Tomaszewski, Rochester Institute of Technology / Computing and Information Sciences; A.C. Tyler, Rochester Institute of Technology / Environmental Science; G. Gaustad, Rochester Institute of Technology / Golisano Institute for Sustainability*

As the demand for higher performance products rises, novel materials like carbonaceous nanomaterials (CNMs) are increasingly integrated into different consumer and industrial products, which affects what part of the life cycle CNMs could be released. It is important to identify the geographic location of production and potential releases to inform knowledge gaps for life cycle impact analysis of emerging materials. Past literature has tried to estimate the locations and concentrations of potential nanomaterial releases throughout a product's life cycle. However, national and global average approaches may underestimate accumulation of releases if they concentrate in a certain area. Since there are varying vulnerabilities depending on the release site (i.e. interaction with threatened habitats, nutrient cycling changes, and trophic level impacts), the location matters and thus informs the magnitude of risk. Because predictive modeling is necessary to estimate likely CNM release patterns and material flows (manufacturing siting, regional adoption of CNM-enabled products, and ecosystem geography), ArcGIS modeling methods were adapted to analyze potential releases from two case study CNM-enabled products. An integrated modeling tool that calculates realistic spatial concentrations of CNMs released from a commercial product (electric vehicle lithium-ion batteries) and an emerging product (organic photovoltaic cells) was developed and compared to empirical ecotoxicity data to determine if there is a chance of emitting high enough concentrations of CNMS that would cause environmental impacts in a targeted siting scenario. Preliminary results show potential CNM exposure from production facilities and disposal sites that are within buffer zones of the Great Lakes watershed and wetland habitats. This integrated modeling and empirical approach is novel to the nanomaterial literature and can help minimize risks to vulnerable ecosystems.

### 179 Estimated release of titanium dioxide from personal care products entering wastewater treatment plants

*F. Wu, University of Wisconsin-Madison / Chemical, Biological and Environmental Engineering; A. Hicks, University of Wisconsin – Madison / Civil and Environmental Engineering; M. Seib, Madison Metropolitan Sewerage District*

Although current regulation indicates titanium dioxide ($TiO_2$) is non-toxic compound, $TiO_2$ nanoparticles (NPs) are considered as an emerging environmental contaminant. Research indicates up to 30% of $TiO_2$ found in personal consumer products (PCPs) are present at nano-scales (one or more dimensions is equal to or less than 100 nm) to achieve applications such as UV protection, coloring, catalysis, and greater sizes serve as a texture modifier in food and PCPs. With the high quantity and wide applications in PCPs, $TiO_2$ is dispersed during use, then entering the waste water treatment plant (WWTP) and ultimately the environment. Traditional studies by directly measuring the $TiO_2$ concentrations in WWTP is localized and difficult to represent $TiO_2$ concentration at large scale. This work utilizes a citizen science approach to generate information as to the quantity of $TiO_2$ entering the WWTP to enhance the knowledge on the life cycle of $TiO_2$ at usage stage, refine the estimates of $TiO_2$ entering the WWTP as a function of the use of PCPs to determine future potential adaptions. In addition, the current study aim is to develop a PCP inventory to list products contain $TiO_2$ (potentially nano-$TiO_2$) for future research and benefit regulators and industry. The objectives are accomplished by surveying PCPs in households from the sewerage district and estimating $TiO_2$ emission at individual household level from use of PCPs. In the survey, information is collected on the brand, number of products, and if contain $TiO_2$, from most commonly used PCPs in the household (such as toothpaste, shampoo, skin care, sunscreen, etc.) along with the demographic information. Survey results are combined with the daily usage and amount of $TiO_2$ in each product to estimate the human exposure and the contribution of $TiO_2$ release to the WWTP from the use of PCPs. $TiO_2$ concentrations in wastewater samples are measured by ICP-MS. Results identify sunscreen to be the product contains the most $TiO_2$. A citizen scientist roundtable meeting will be held to present the results and gain insight from the citizens to future solutions as the next phase. The information generated throughout this study is useful to prioritize future research, such as the life cycle of $TiO_2$ containing consumer products, predict the fate and transport of $TiO_2$ released from PCPs, and possibly refine future regulations based on the applications and pathways that are most likely to impact human health and the environment.

### 180 Insights from life cycle assessment of nano-silver enabled consumer products

*A. Hicks, University of Wisconsin – Madison / Civil and Environmental Engineering*

Silver has been utilized for its antimicrobial properties since antiquity. Nano-scale silver (nAg) with dimensions of less than 100 nanometers (nm) is one of the most commonly used nanoparticles in consumer products due to its antimicrobial efficacy which has been found to be enhanced compared to bulk silver. These products include textiles, food storage containers, sprays, toothpaste, among others, with the goal of providing an antimicrobial characteristic to these products. A major question has been whether the benefits bestowed by the addition of nAg to consumer products outweighs the environmental costs. Life cycle assessment (LCA), a systematic tool for determining the environmental impacts of products and processes throughout their lifetime, has been applied to evaluate the environmental impacts of nAg enabled products. In most instances the additional environmental burden due to the incorporation of nAg is relatively small, however, that is not universally true across all products and environmental impact categories. This work utilizes life cycle assessment to frame the discussion as to the relative environmental costs (or impacts) and benefits (such as antimicrobial efficacy) enabled through the addition of nAg to consumer products, highlighting multiple consumer products. The findings suggest that although the additional environmental impact is often small, in some instances, due to the antimicrobial ineffectiveness of the nAg, that the nanoenabling is not worthwhile. This may serve as the starting point for a framework to determine when the benefits of nano-enabling consumer products with nAg outweigh the costs.

**181 Nanoparticle Detection in Environmentally Relevant Matrices and Biota Using Single Particle ICP-MS**

*M.E. Ellefson, 3M Company / 3M Environmental Laboratory; C.Q. Chan, 3M Company / Corporate Reseach Analytical Lab; B.T. Mader, 3M Company / Environmental Laboratory*

Engineered nanoparticles frequently are used as additives to consumer products to enhance product properties. Understanding the environmental fate and impact of engineered nanoparticles relies on the ability to characterize them at relatively low levels in complex media and biota, which often contains additional naturally occurring nanoparticles. We present the application of a recently developed analytical technique which utilizes elemental analysis of individual nanoparticles using inductively coupled plasma mass spectrometry (spICP-MS) to characterize gold and silver nanoparticles in environmentally relevant water samples including ground water, industrial wastewater, and ecotoxicology test media. The method is capable of detecting nanoparticles of 10-100 nm diameter at part-per-trillion (ppt) levels in environmentally relevant aqueous solutions. Following instrument characterization, the spICP-MS was used to assess the fate of gold nanoparticles in a solution containing daphnia magna. Insights into dose verifications obtained by spICP-MS will be discussed as well as the method's performance and the advantages of using spICP-MS for dose verification and determining environmental fate of gold and silver nanoparticles in complex environmentally-relevant sample matrices.

**182 Altering silver nanowire diameter for intelligent re-design and recycling to improve the safety and sustainability of touchscreen technology**

*D. Arndt, University of Florida / Physiology; D. Toybou, S. Lehmann, University of Grenoble Alps; B. Omana, University of Lille; L. Charlet, University of Grenoble Alps; A. Hofmann, University of Lille; B. Gilbert, Lawrence Berkeley National Laboratory; C. Vulpe, University of Florida, Gainesville / Department of Physiological Science and the Center for Environmental and Human Toxicology*

Silver nanowires are replacing indium tin oxide in touchscreen applications, but it is not clear if silver nanowires will exhibit behaviors that are different from their spherical counterparts in biological systems. This project focuses on human and environmental impacts of silver nanowires (AgNWs) as a consequence of their synthesis and application in touchscreen technologies. The goals of this project are to determine if the environmental fate and impacts of AgNWs differ from spherical silver nanoparticles, if AgNWs are released from touchscreens during aging or environmental exposure, and if silver can be reclaimed from touchscreens after disposal. This project is part of a transnational collaboration that highlights multi-disciplinary perspectives to inform risk management strategies in the U. S. and Europe. AgNW synthesis and characterization are centralized at the University of the Grenoble Alps, France to decrease AgNW variability among participating laboratories. Results indicate that AgNW diameter is a key factor that influences AgNW toxicity to humans and aquatic organisms. Thick AgNWs (90 nm diameter; 10 µm length) induced significantly more cytotoxicity compared to thin AgNWs (30 nm diameter; 10 µm length), and this was determined in multiple cell lines (mouse fibroblasts, rainbow trout gill and gut cells) looking at a number of endpoints (ATP production, membrane integrity, ROS production, mitochondrial membrane potential, etc.). X-ray microscopy images reveal mechanical crumpling of thin AgNWs after cellular uptake, while thick AgNWs maintain their rigid structures. These different mechanical behaviors after cellular uptake can explain their different toxicity in cells, as crumpled AgNWs are less likely to damage intracellular structures. Whole organism assays on rainbow trout embryos and fry indicate some toxicity of AgNWs, but no significant differences between thick and thin AgNWs were observed. Weathering experiments indicate the corrosion of AgNW thin films is possible under certain environmental conditions despite the coating of the AgNW film by a protective resin, and an electrochemical technique for reclaiming Ag from AgNW-enabled technology has shown promising results. Future work will focus on the bioaccumulation and trophic transfer of AgNWs in an aquatic system, and RNAseq to further evaluate the mechanisms of differential AgNW-diameter related toxicity.

**184 Trophic transfer of differentially charged CeO2 nanoparticles from tomato plants to hornworms**

*J. Li, University of Kentucky / Plant and Soil Science; J. Unrine, University of Kentucky*

The entry of manufactured nanomaterials (MNM) into the food webs has the potential for far-reaching impacts on ecosystems. Our previous studies and those of others have demonstrated trophic transfer of MNMs. However, our knowledge is still incomplete regarding the dietary transfer of MNM along the food chain and the specific role of particle surface chemistry. This study investigated the dietary uptake and elimination of polymer-coated $CeO_2$ nanoparticles (NPs) carrying a net positive, neutral or negative charge in a simulated food chain consisting of the tomato plant (*Solanum lycopersicum* cv Micro-Tom) and the tobacco hornworm (*Manduca sexta).* Hydroponically cultivated tomato plants were exposed to the three different types of $CeO_2$ NPs at non-toxic concentrations for 14 days. Freshly cut leaves were used to feed the hornworms. After 7 days of feeding allowing the uptake of $CeO_2$ NPs from the food, elimination of $CeO_2$ NPs occurred by feeding leaves from untreated plants to the hornworms. Randomly selected hornworms were sacrificed and analyzed at various time points throughout the process to obtain a time course of Ce dynamics. Despite no observed overall biomagnification across trophic levels, these differentially charged CeO2 NPs had higher bioaccumulation factors than that of ionic $Ce^{3+}$. The uptake-elimination dynamics were influenced by the surface charge of the NPs. Positively charged NPs had higher bioaccumulation factors and assimilation efficiencies but lower elimination rate than neutral and negatively charged CeO2 NPs. These results provide important evidence that physico-chemcial properties such as surface charge have a great impact on the trophic transfer and uptake-elimination dynamics of MNM within terrestrial food chains.

## Micro-organisms and Biopesticides in Crop Production: Use and Environmental Safety Considerations

**185 Future products of biotechnology and needs for risk analysis science: Findings and recommendations of a National Academies of Science study**

*S.P. Bradbury, Iowa State University / Natural Resource Ecology and Management*

In July 2015, the Office of Science and Technology Policy in the Executive Office of the President initiated an effort to modernize the U.S. government's regulatory system for biotechnology products. As part of this effort, a committee of the National Academies of Sciences, Engineering, and Medicine was tasked to forecast likely future products of biotechnology over the next 5-10 years and the scientific capabilities, tools, and expertise needed by the U.S. regulatory agencies to ensure efficient and sound risk analyses. The committee's information gathering efforts included dialogue with the U.S. Department of Agriculture, Environmental Protection Agency, Food and Drug Administration, and other Federal agencies; public meetings; and review of the literature and recent Academies' reports on gene drives, genetically-engineered crops, and the industrialization of biology. The committee evaluated technological, economic and social drivers associated with products likely to enter the market over the next 5-10 years. The Committee also evaluated whether future biotechnology products could pose different types of risks relative to existing products and organisms. The Committee's report was released in March 2017. The report concluded that the bioeconomy is growing rapidly and the number and complexity of future products, and diversity and number of new product developers, has the potential to overwhelm the U.S. regulatory system. The report provides fourteen specific recommendations for how the U.S. government can improve its capabilities to evaluate future products through advances in regulatory governance and risk analysis techniques. The recommendations fall into three broad themes: a) enhance scientific capabilities and tools in the natural, social and regulatory sciences; b) develop prototype approaches for assessing risks and benefits, with public participation and external peer review, for future unfamiliar and complex products identified through horizon scanning; and c) connect biotechnology research and development pipelines with proactive advances in regulatory science. The full report titled, Future Biotechnology Products and Opportunities to Enhance Capabilities of the Biotechnology Regulatory System, is available at http://nas-sites.org/biotech/

**186 Characterization and manipulation of crop microbiota**

*J. Leveau, University of California – Davis / Department of Plant Pathology*

Plants are colonized by a diverse community of microorganisms known as plant microbiota. The interactions that these microorganisms have with each other and with their plant host determine the health of the plant and in the case of commercially important crops, the yield and quality of the plant product. Using processing tomatoes as an example, this presentation will explore the question of what constitutes a 'healthy' microbiota and what can be done to fix an 'unhealthy' one. More specifically, it will present an in-depth profile of the bacterial and fungal microbial communities in the soils and on the roots of processing tomato plants as it relates to field location and the application of various chemical and biological soil amendments. Also presented will be the results of a study into the utility of bacteria from the genus Collimonas to protect tomato plants from soilborne fungal pathogens.

**187 Global Survey of Microbial Pesticide Regulation and CropLife International 's Microbial Pesticide Safety Framework**

*R. Garnett, CropLife International; M. Herrero, Valent; M. Hey, Monsanto; N. Hubbard, Corteva; R. Kneen, Bayer; M. Liebergesell, FMC; D. Munday, Sumitomo; L.S. Ortego, Bayer CropScience / Environmental Toxicology and Risk Assessment; S. Rutherford, European Crop Protection Association ECPA; J. Vialaneix, BASF; A. Scarr, Syngenta*

Microbial pesticides are a type of product derived from naturally-occurring organisms which are used to prevent, destroy, repel or mitigate a pest. They can be eukaryotic in nature such as protozoa, algae, and fungi or prokaryotic such as Eubacteria and Archaebacteria. They can also be parasitically replicating microscopic elements such as viruses. Microbial pesticides are used throughout the world, but regulation can be quite different country to country. Many countries apply their chemical regulation system to microbial pesticides, but the testing and risk assessment requirements for chemicals are generally inappropriate for the regulation of these products, e.g., the chemical testing guidelines do not include provisions for determining pathogenicity. A few jurisdictions have microbial-specific regulation including US, EU, China, Japan, and Brazil. Other countries may have very little regulation of these products and require little if any environmental safety data or risk assessments. CropLife International developed an environmental safety framework for microbial pesticides in order to aid member companies in evaluating the environmental safety of their products. In this framework, a base set of information is described which can be used to evaluate environmental safety and risk and the need for additional testing. It is recommended that this information may come from reliable and relevant peer-reviewed literature when available *in lieu* of performing additional testing. An appropriate conceptual model also should be used to determine if there is exposure to the compartment of concern; the safety evaluation should focus on organisms that may be exposed. In this presentation, a brief global survey of various environmental evaluation requirements and approaches will be presented. The CropLife International framework will be described focusing on the approach for viable bacterial and fungal microbial pesticide environmental safety evaluation.

**188 Ecological Risk Assessement for Microbial Pesticides in the US**

*S. Borges, USEPA / Biopesticides and Pollution Prevention Division*

The U.S. Environmental Protection Agency (EPA) defines biopesticides as certain types of pesticides that are derived from such natural materials as animals, plants, bacteria, and certain minerals. The EPA recognizes that biopesticides have certain unique properties and benefits, and has developed a specific regulatory approach for these types of pesticides. Microbial pesticides are a category of biopesticides that consist of eukaryotic (e.g., fungi, algae, protozoa) and prokaryotic (e.g., bacteria) microorganisms, as well as autonomous replicating microscopic elements (e.g., viruses). General concepts of ecological risk assessment apply to microbial pesticides, but special considerations must be made in exposure assessment and nontarget testing to account for their potential viability in the environment and pathogenic effects. The EPA has developed specific guidelines for nontarget testing for microbial pesticides, which capture these special considerations and are required according to a tiered scheme. This testing is based on guidelines developed for chemical pesticides, but takes into account the unique nature of microbials in specific methods and/or general approach. While some challenges exist, the EPA's approach has proven to be a viable balance between data needs for risk assessment and regulatory burden.

**189 Considerations for Ecological Testing and Assessment of dsRNA Agricultural Products**

*J. Fischer, Monsanto Company / Global Regulatory Sciences*

The discovery and development of double-stranded RNA (dsRNA) products that confer protection from insect pests through a new mode of action have the potential to provide significant value in agriculture. The sequence specific nature of dsRNA allows these products to target pest species with a high level of specificity, while mitigating risk to non-target organisms. Registration and commercialization of these products requires comprehensive science-based ecological risk assessments to ensure these products are safe for the environment. As is the case with traditional crop protection products, ecological risk from a dsRNA insect control product is a function of potential harm and environmental exposure. Proposed use patterns for a dsRNA product such as expression by a genetically-modified crop or topical application inform the relevant routes and potential duration of exposure. Such considerations in addition to mode of action, activity spectrum and bioinformatics analysis can provide guidance for appropriate non-target organism testing. This presentation will provide examples of how this scientifically relevant information can be used to inform problem formulation and how problem formulation can be used to develop an ecological assessment plan for dsRNA products.

**190 Dissipation of dsRNA in an aqueous system**

*J.R. Coats, Iowa State University / Entomology; C. Wong, V.C. Albright, Iowa State University / Department of Entomology*

The use of double stranded RNA (dsRNA) to induce RNA interference in pests has proven effective, and its potential use to control insect pests is being examined closely. This study examined the persistence of a non-bioactive dsRNA sequence in aquatic systems with water over sediment. Methods: Test systems consisting of purified water and sterilized sediment, sterilized pond water and sterilized sediment, and active pond water over active sediment were all inoculated with the dsRNA applied to the water phase. Samples were extracted via a proteinase K digestion from the sediment and the overlying water separately. Sample systems were allowed to incubate for time periods up to 14 days. Dissipation of dsRNA was determined by QuantiGene® 2.0 Singleplex assay kit (Affymetrix).

The kit was tailored by the manufacturer to match this specific dsRNA sequence. Results/conclusion: For all experimental systems, dsRNA recovery was reduced to background levels by 96 hours post-inoculation. Movement from water into the sediment was minimal, with at most 3% of the initial dsRNA found in the sediment of the system. The half-life of the sequence was similar for all systems, ranging from 56 to 72 hours, which suggests that abiotic factors alone can degrade dsRNA in the environment.

**191 Challenges in Testing Biopesticides in Conventional Laboratory Ecotoxicology Studies**

*H.O. Krueger, EAG Laboratories; D. Brougher, J. Griebel, EAG Laboratories / Aquatic Toxicology*

Standardized testing procedures have long been established for testing aquatic and terrestrial organisms. These tests have been optimized for conventional pesticides where the physical/chemical properties and routes of exposure of the test substances are well understood. The rules for setting test concentrations for conventional tests are well understood, but additional guidance is needed for biopesticides. Quantification and confirmation of the test item is not as straightforward as conventional testing. Microbial materials require plating and results need to be converted from the number of colony forming units to mg product/L. In aquatic testing the limit of solubility is often used to determine the highest test concentration tested. For many biopesticides, solubility does not really apply and the test material may actually grow and increase over the course the test. Another issue is that in aquatic testing solvents may be used to get materials in solution. Such solvents can be highly toxic to biopesticides limiting the use of carriers in test systems. Additionally, after adding a biopesticide to a test system in an aquatic test, either the test item or its carrier often reduces the visibility in test solutions making observations difficult during the test. Dissolved oxygen levels in water can also be of concern and gentle aeration from test initiation is advised. Products that are proteins can denature making it hard to maintain test concentrations. Microbial seed coatings also are challenging. How do you set test concentrations for chronic honey bee tests when the test material will not translocate in plants and end up in nectar or pollen? Another consideration in bee testing is the antimicrobial properties of royal jelly. As was done with conventional materials there is a need to work collaboratively among academia, government, and industry to develop better guidance for testing.

**192 Safety Testing Strategies To Evaluate The Potential Effects Of Biopesticides Used In Crop Protection Products On Aquatic Organisms**

*A.E. Fournier, M.J. Bradley, L. Sayers, R.C. Biever, Smithers Viscient / Department of Ecotoxicology*

Biopesticides as defined by the USEPA are divided into three general categories: biochemicals, which are naturally occurring substances, microorganisms or microbial pesticides, and plant-incorporated protectants (PIPs). The USEPA first issued guidance for testing microbial pest control agents (MPCA) in 1983. While it is recognized that these organisms are unique with specific modes of action, the guidance is vague and has remained relatively unchanged over the last 35 years. Other regions in the world typically look to the US in the testing and risk assessment process for MPCAs and thus better guidance in these regions is not available. The guidance documents are brief and tend to take standard chemical testing principles and procedures, and then applies those strategies to MPCAs. This typically leads to having to make significant modifications to exposure systems used in chemical testing to assure that the MPCAs are dosed properly and stay suspended in the water column, without causing physical effects to the organisms. Additionally, confirmation of this dosing and suspension through chemical specific analysis or microbial evaluation has presented an area for further challenges with little guidance. Another unique challenge in safety testing of MPCAs is that evaluation of pathogenicity is required in addition to general toxicity, thus the exposures need to be longer in duration, with a gross necropsy at the termination of the exposure. We will present an overview of the aquatic testing requirements, identifying the test substance and necessary controls, some of the modifications utilized to manage exposures, challenges in measuring exposure and look at some typical outcomes of aquatic testing with MPCAs. Methodology used in the testing of MPCAs will be compared to methods used in testing biochemicals.

## Birds Under Stress: Impacts of Chemical Exposure and Environmental Changes – Part 1

**193 Spatial differences in mercury exposure in blood and eggs of a declining seabird in Atlantic Canada: Leach's storm-petrel**

*N.M. Burgess, A. Hedd, Environment & Climate Change Canada / Science and Technology Branch; I.L. Pollet, Dalhousie University; R.A. Mauck, Kenyon College / Biology Department; R.A. Ronconi, C. Gjerdrum, Environment and Climate Change Canada / Canadian Wildlife Service; L. McFarlane Tranquilla, Bird Studies Canada; C.M. Burke, Memorial University of Newfoundland / Psychology Department; D. Shutler, Acadia University / Biology*

Leach's storm-petrel (*Oceanodroma leucorhoa* = *Hydrobates leucorhous*) is a small seabird species that was listed as globally vulnerable on the IUCN's Red List of Threatened Species in 2016. Breeding populations have declined more than 30% over the last three generations in Atlantic Canada. This migratory seabird species faces multiple stressors in their breeding and wintering habitats. Previous studies had revealed that elevated mercury exposure may be one such stressor. As part of an assessment of the role of methylmercury toxicity in these population declines, we measured mercury concentrations and stable carbon, nitrogen and sulphur isotope ratios in the eggs and blood of adult Leach's storm-petrels at five breeding colonies across Atlantic Canada. Eggs were collected soon after laying in 2016 and 2017. Blood was collected from incubating adults (in different nesting burrows from the egg collections) about a month later. We measured total mercury and stable carbon ($\delta^{13}C$), nitrogen ($\delta^{15}N$) and sulphur ($\delta^{34}S$) isotope ratios in egg contents and whole blood. Geometric mean mercury concentrations in the blood of adult Leach's storm-petrels (n=191) were significantly greater at two colonies around Newfoundland (Baccalieu 1.10 µg/g wet wt. and Gull 0.99 µg/g) than at three colonies in the Bay of Fundy and Scotian Shelf (Country Island 0.83 µg/g wet wt, Bon Portage 0.76 µg/g and Kent 0.41 µg/g). A slightly different spatial pattern emerged from the storm-petrel eggs (n=106), where the geometric mean mercury concentrations were significantly greater at three colonies (Baccalieu 2.52 µg/g dry wt., Gull 2.53 µg/g and Bon Portage 2.15 µg/g) than at Kent Island in the Bay of Fundy (1.53 µg/g dry wt.). Nevertheless, the geometric mean blood and egg mercury concentrations at each colony were highly correlated (Pearson $R = 0.96$, $p = 0.01$). We will discuss the insights provided by $\delta^{13}C$, $\delta^{15}N$ and $\delta^{34}S$ for interpreting differences in blood and egg mercury concentrations among and within colonies. We will also discuss the potential toxicological significance of the observed blood and egg mercury concentrations for Leach's storm-petrels breeding in Atlantic Canada. Leach's storm-petrel can be used as an indicator of methylmercury dynamics in marine mesopelagic food webs.

**194 Mercury exposure and altered parental nesting behavior in a free-living songbird**

*A. Hartman, J.T. Ackerman, M. Herzog, US Geological Survey / Western Ecological Research Center*

Reproduction is among the most sensitive endpoints of methylmercury exposure in birds. At lethal concentrations, methylmercury exposure can impair reproduction through direct mortality of offspring. However, the mechanisms by which sublethal methylmercury concentrations impair avian reproductive success are unclear. We investigated maternal mercury concentrations and maternal incubation behaviors of 59 free-living tree swallows (*Tachycineta bicolor*) in the Central Valley of California. We observed differences in tree swallow incubation behavior and performance with increased maternal mercury concentrations. Females with higher mercury concentrations spent significantly less time on the nest, took more frequent and slightly shorter incubation recesses, and were more likely to take recesses that resulted in substantial nest temperature decreases than females with lower mercury concentrations. As a result, by the end of the typically 14-day incubation period, we predicted that eggs of females with the highest mercury concentrations cumulatively lost almost one day of incubation time compared to the eggs of females with the lowest mercury concentrations. Less time spent incubating and caring for eggs could lengthen the incubation period, reduce egg hatching success, and decrease nest survival. Our results are among the first to demonstrate that methylmercury exposure can alter parental nesting behaviors in a population of free-living songbirds.

**195 Hepatic transcriptome variations in three avian species reflect their susceptibility to mercury**

*N.K. Karouna-Renier, USGS Patuxent Wildlife Research Center; R.S. Cornman, U.S. Geological Survey, Fort Collins Science Center*

Previous studies have confirmed clear differences in the sensitivity of various bird species to methylmercury. These studies have ranked species based on survival (LC50) from laboratory exposures *in ovo* to injected methylmercury (MeHg). Although wide variation in LC50 exists, the causes of these variations in sensitivity are unknown. Organisms have a variety of mechanisms that protect against mercury toxicity. Genetic variations and gene expression patterns related to these processes influence susceptibility and allow less sensitive species to survive, while their more sensitive counterparts succumb. In order to describe the mechanisms and strategies that underlay the differences in sensitivity to methylmercury, we used RNAseq to compare hepatic RNA expression patterns in three bird species that show varying sensitivity to mercury: laughing gull (*Larus atricilla* low sensitivity), American kestrel (*Falco sparverius* – high sensitivity) and osprey (*Pandion haliaetus* – high sensitivity). Eggs were injected with a single dose of MeHg (final concentration = 0.05, 0.1, 0.2, or 0.4 ug/g) to simulate maternal deposition of mercury into the egg. Liver was collected and transcriptome profiles were examined. We found striking differences in the number and identity of differentially expressed genes between the three species at each common dose. For example, at 0.1 ug/g/ MeHg, 4525 differentially expressed genes (DEG; 356≥log2 fold change) relative to oil-only controls were identified in laughing gulls (adjusted p-value < 0.05). Osprey (12 DEG, 11≥log2 fold change) and kestrels (95 DEG, 66 ≥log2 fold change) exhibited much lower, and qualitatively different expression of mRNA, suggesting that laughing gulls are better able to mount a response to Hg than their more sensitive counterparts.

**196 Does anticoagulant rodenticide exposure have lasting effects on sensitivity to subsequent anticoagulant rodenticide exposure in raptors?**

*B.A. Rattner, USGS Patuxent Wildlife Research Center; K. Horak, USDA; S.F. Volker, USDA / APHIS; T. Bean, Smithers Viscient / Avian Toxicology; M.E. Barton, University of Maryland / Environmental Science and Technology; S.L. Schultz, USGS Patuxent Wildlife Research Center / Beltsville Lab; X. Chen, J. Tie, University of North Carolina at Chapel Hill / Biology; J.S. Lankton, USGS National Wildlife Health Center*

A seminal question in wildlife toxicology is whether exposure to an environmental contaminant can evoke subtle long-lasting effects on body condition, physiological function and survival. An often-cited study in laboratory rats demonstrated that a single oral dose of the second-generation anticoagulant rodenticide (SGAR) brodifacoum prolongs blood clotting time for just a few days, but weeks later when rats were exposed to the first-generation AR (FGAR) warfarin, coagulopathy was more pronounced in brodifacoum-exposed rats compared to naïve rats exposed to warfarin. This observation was attributed to partial inhibition of hepatic microsomal vitamin K epoxide reductase (VKOR) activity for weeks after exposure (Mosterd & Thijssen 1991). To investigate this phenomenon in non-target birds, studies were undertaken in American kestrels (*Falco sparverius*) to demonstrate brodifacoum toxicity, and subsequently examine effects on clotting time during repeated AR exposures. Kestrels fed diets containing 0.3, 1 or 3 mg brodifacoum/kg ww for 7 days exhibited dose-dependent evidence of bruising, hemorrhage, and coagulopathy. When a 7-day dietary brodifacoum exposure at 0.5 mg/kg diet was terminated, prolonged clotting times were restored to baseline values within a week. Brodifacoum appears to target the same enzyme, VKOR, in American kestrels as in mammals, and has similar inhibition efficiency for VKOR containing hepatic microsomes (IC50 of 0.22 µM in kestrels and 0.15-0.26 µM in mammals). Since the residual brodifacoum concentration in kestrel hepatic microsomes (< 0.02 µM) is much lower than the IC50, we were not able to relate in vitro VKOR activity inhibition to in vivo signs of intoxication in kestrels as reported in the laboratory rat. In order to examine the hazard associated with sequential exposure to multiple ARs, kestrels were initially exposed to an untreated diet or diets containing either the FGAR chlorophacinone (1.5 mg/kg) or the SGAR brodifacoum (0.5 mg/kg) for 7 days. Then, following a 7-day recovery period, all birds were challenged with a low dose of chlorophacinone for 7 days (0.25 mg/kg diet, previously demonstrated to evoke minimal effects on clotting time; Rattner et al. 2015). At these exposure levels, long-lasting effects of AR exposure and residues on clotting time were not apparent. Additional studies using environmentally realistic doses and route of exposure are underway to further test this hypothesis.

**197 Avian interspecific differences in rodenticide sensitivity: Amino acid sequence and mRNA expression ratio of VKORC1 and VKORC1L1**

*S. Nakayama, A. Morita, Hokkaido University; Y. Ikenaka, Hokkaido University / Graduate School of Veterinary Medicine; Y.K. Kawai, Obihiro University of Agriculture and Veterinary Medicine; K. Takeda, Hokkaido University; H. Mizukawa, Hokkaido University / Graduate School of Veterinary Medicine; C. Ishii, Hokkaido University; K. Saito, Y. Watanabe, Institute for Raptor Biomedicine Japan; M. Ito, N. Ohsawa, Sapporo Maruyama Zoo; M. Ishizuka, Hokkaido University / Graduate School of Veterinary Medicine*

Worldwide use of anticoagulant rodenticides (ARs) for vertebrate pest control has frequently led to the unintentional exposures of non-target animals, especially raptors, to these poisons. The median lethal dose (LD50) for anticoagulant rodenticides (ARs) among animals suggest that avian species seem more resistant to ARs than mammals. However, the LD50 for ARs in the American keestrel (Falco sparverius) is lower than that in poultry. Considering both the low values of LD50 in raptors and the frequent poisoning of non-target wild birds, especially raptors, implies raptors have different susceptibility to ARs than poultry. These facts suggest that it is inappropriate to extrapolate the LD50 data from poultry to the risk assessment for raptors. In order to reveal the mechanism of the incidents, this study focused on the avian vitamin K 2, 3-epoxide reductase (VKOR) that is the target protein of ARs. We clarified the interspecific differences in VKOR activity and inhibition related to amino acid sequence and mRNA expression of VKORC1 and VKORC1-like1 (VKORC1L1). VKOR activity of owls, hawks, falcon and surprisingly, canaries, was lower and inhibited by warfarin more easily than that of chickens and turkeys. The amino acid sequence of VKORC1 and VKORC1L1 implied that the value of Ki for VKOR activity to ARs could depend on the amino acid at position 140 in the TYX warfarin-binding motif in VKORC1, and other amino acid mutations in VKORC1L1. The mRNA expression ratio of VKORC1:VKORC1L1 differed between turkey (8:1) and chicken (2:3) liver. Hence, both the Ki of specific VKORC1 and VKORC1L1, and the mRNA expression ratio would cause avian interspecific difference of the VKOR inhibition ratio. Our study also demonstrated the high inhibition ratio of raptor VKOR activities and surprisingly that in canaries as well. These factors are the most likely to contribute to the high sensitivity to ARs found in raptors. Furthermore, our strategy is worth identifying novel avian species such as canaries which could be susceptible to ARs. Our study will help reveal the mechanism of secondary poisonings in raptors by ARs.

**198 Tracking the atmospheric exposure to halogenated flame retardants on the back of a gull**

*M. Sorais, UQAM – TOXEN / Biological Sciences; M.J. Mazerolle, Laval University / Wood and Forest Science; J. Giroux, J. Verreault, University of Quebec at Montreal / Department of Biological Sciences*

A large suite of halogenated flame retardants (HFRs) including polybrominated diphenyl ethers (PBDEs) and certain emerging compounds have been detected in tissues and eggs of ring-billed gulls (*Larus delawarensis*) nesting in the Montreal area (QC, Canada). Elevated plasma concentrations of the highly hydrophobic DecaBDE in male gulls were found to correlate with the time spent in specific foraging habitats such as landfills. Landfills are known hotspots of emissions for airborne HFRs that are efficiently transported in the atmosphere. Hence, gulls feeding in and around landfills can be highly exposed to these chemicals via dust and particle ingestion and inhalation. However, no method has as yet been developed to quantify this type of exposure. Therefore, we recently designed a miniature passive air sampler that can be carried by gulls for the collection of gas- and particle-phased HFRs in air. The present study aimed to: a) assess the spatial associations between the accumulation rates of individual HFRs collected in bird-borne passive air samplers and the different habitats visited by gulls, and b) model the specific contribution of landfill usage in the Montreal area to the accumulation rates of HFRs in the samplers. We equipped 67 nesting gulls with a miniature passive air sampler and a GPS datalogger in order to collect HFRs in air while monitoring their movements during two weeks. The main PBDE congeners detected in the samplers were the major components of the commercial mixtures PentaBDE (BDE-47 and -99) and DecaBDE (BDE-209). Also, a few emerging HFRs (hexabromobenzene, Dechlorane-604 CB and Dechlorane plus) were detected, although at low levels. Important variations in accumulation rates were found between individual samplers for PentaBDE, OctaBDE and DecaBDE congeners. Spatial analysis showed that the accumulation rates of PBDE mixtures were more aggregated than emerging HFRs around punctual local sources, such as landfills. The accumulation rates of all PBDE mixtures and Dec604-CB were indeed found to positively correlate with the proportions of time spent by gulls in landfills. However, such correlations were not observed for the emerging HFRs, which suggests alternative sources for these chemicals. This is the first study to address interindividual variations in atmospheric HFR exposure in birds, while providing valuable information on the local sources of these ubiquitous chemicals in a highly urbanized region.

**199 Extracts of passive samplers deployed in variably contaminated wetlands in the Athabasca oil sands region elicit unique effects in avian hepatocytes**

*D. Crump, S. Chiu, K. Williams, B. Pauli, L. Mundy, Environment and Climate Change Canada / National Wildlife Research Centre*

Deployment of passive samplers in wetlands within the Athabasca oil sands region represents an effective means to conduct environmental monitoring without requiring the collection of wildlife tissue samples. In this study, graded concentrations of semi-permeable membrane device (SPMD) extracts, deployed at 4 wetlands with variable burdens of polycyclic aromatic compounds (PACs), were administered to chicken and double-crested cormorant (DCCO) embryonic hepatocytes. Effects on 7-ethoxyresorufin-*O*-deethylase (EROD) activity and mRNA expression were determined. PAC concentrations were variable among sites and alkyl-PACs were more abundant in SPMDs than parent compounds. EROD activity and *Cyp1a4* mRNA expression permitted the ranking of wetland sites based on aryl hydrocarbon receptor-mediated endpoints (e.g. EROD $EC_{Thr}$ was lowest and *Cyp1a4* mRNA induction highest in extracts from the wetland with the greatest PAC concentrations). Two avian ToxChip PCR arrays (chicken and DCCO) provided a more exhaustive transcriptomic evaluation across multiple toxicological pathways following exposure to the SPMD extracts. The wetland sites with the greatest PAC concentrations led to the alteration of the most genes on the ToxChip arrays (e.g. 12-15/43 genes on the chicken ToxChip). Exposure of avian hepatocytes to SPMD extracts from variably contaminated wetlands highlighted traditional PAC-related toxicity pathways as well as other novel mechanisms of action. Extrapolation to real world exposure scenarios must consider the bioavailability of the extracted PACs contained in the SPMDs compared to those in exposed organisms; however, such approaches show promise in terms of identifying hotspots of chemical concern in the natural environment.

**200 Polycyclic aromatic hydrocarbon exposure impacts on Sanderling pre-migratory fuelling and migration**

*K. Bianchini, University of Saskatchewan – Toxicology Centre / Toxicology; D. Newstead, Coastal Bend Bays & Estuaries Program; C.A. Morrissey, University of Saskatchewan / Biology*

Long-distance migratory birds can make non-stop flights of thousands of kilometers without access to supplementary food or water. Accomplishing these extreme endurance feats requires that birds rapidly store adequate fuel loads prior to departure. Efficient fuelling is critical for migratory birds because fuel loads and fuelling rates affect reproductive performance and survival during migration. The polycyclic aromatic hydrocarbons (PAHs) found in oil pollution have the potential to interfere with pre-migratory fuelling physiology. However, a link between PAH exposure and impaired pre-migratory fuelling has yet to be established. We used a combination of captive and field techniques to determine if PAH contamination affects pre-migratory fuelling and the subsequent migration of Sanderling (*Calidris alba*), a long-distance migratory shorebird. For captive experiments, we orally exposed 49 wild-caught Sanderling with a commercial PAH mixture over a 21-day period of pre-migratory fuelling. In the field, we measured the mass and plasma metabolite levels of 170 Sanderling at six staging sites in Gulf of Mexico (GOM) and over 375 Sanderling in Chaplin Lake, Saskatchewan. Coded radio telemetry tags were attached to a subset of birds to track migratory movements using the Motus radio-telemetry array. At all staging sites, we measured sediment total PAH concentrations to assess oil contaminant exposure. Captively dosed Sanderling showed reduced pre-migratory mass gains relative to controls, which were associated with reduced serum bile acid and elevated serum lipase and creatine kinase concentrations. Similarly, in the field, plasma metabolite levels revealed that Sanderling in Louisiana, where sediment PAH concentration were the highest, had the lowest fuel deposition rates. Radio telemetry data showed that fuel loads were negatively correlated with stopover durations and departure dates, where leaner birds departed later. Moreover, individuals that departed later from the GOM also showed later arrival and subsequent departure dates in Saskatchewan. Our results thus confirm that PAH exposure can impair avian pre-migratory fuelling. We also show that impaired fuelling can cause delays in migration that carry over from one staging site to the next. This work thus highlights the significant threat of PAH exposure to long-distance migratory birds.

## Translating Environmental Science into Improved Outcomes and Policy

**201 Translational research success stories: The role of industry, academic, and agency collaboration**

*K. O'Reilly, Exponent / Environmental and Earth Science*

From leaking storage tanks at a local service station to large oil spills, the fate of petroleum in the environment interests the public, policy makers, and those in the oil industry. Research on the fate and risks of hydrocarbons has long been conducted by scientists associated with academic institutions, environmental agencies, trade groups, consulting firms, and oil companies. Throughout the modern environmental era, collaboration across these entities has been critical in integrating the results of basic research into regulatory policy and remediation technologies.

Collaboration provides a conduit from the bench through pilot systems and field-testing to real world sites and facilities. This presentation will discuss the role of collaborative translational research from the development of monitored natural attenuation through the growing use of non-targeted chemical analysis to assess risks associated with petroleum biodegradation intermediates in the environment. The presentation will also highlight the application of collaborative research to improve regulatory policy and technical guidance.

**202 Objective-based regulation of offshore oil and gas in Australia**

*T. Reitsema, NOPSEMA*

This presentation provides an introduction to the approach used by Australia's National Offshore Petroleum Safety and Environmental Management Authority (NOPSEMA) in regulating 'planned discharges' (such as produced water or drill cuttings/mud) from the offshore oil and gas industry. NOPSEMA commenced its environment function in 2012, and administers an objective-based form of regulation. This regulatory method varies from the prescriptive regulatory approach, in that responsibility for ensuring protection of the environment lies with those who create the risk. An objective-based regulatory regime sets high level requirements that must be achieved, but does not specifically prescribe how those requirements must be met. Requirements are determined through the assessment process, and are set within accepted environment plans which are legally binding documents. The objective-based regulatory approach offers benefits such as scalability and flexibility relative to the risk profile of the activity, as well as encouraging adoption of best practice management. It also raises challenges such as the application of the environmental risk assessment process to drive acceptable environmental outcomes, and the principle of reduction of impacts and risks to ALARP (as low as reasonably practicable). For example, with previous prescriptive legislative requirements for oil in water content for produced water being removed there is a benefit in ability to drive best practice, with a challenge of needing to ensure that standards that are set are in fact acceptable and ALARP. This presentation will provide information on the regulatory approach used by NOPSEMA, and provide an opportunity for dialogue, also in relation to approaches used in other jurisdictions.

**203 Reform of Environmental Regulations – What's this got to do with environmental toxicology and risk assessment?**

*T.S. Bingman, DuPont Corporate Remediation; R.G. Stahl, E.I. DuPont de Nemours and Company / Corp Remediation; B. Grimsted, Peoneer Technologies Corp; C. Waldron, Pioneer Technologies, Inc.*

A key initiative of the current administration is streamlining environmental regulations in order to increase efficiency and lower regulatory impacts on American industry. In early 2017, Executive Orders 13771 and 13777 were issued outlining steps in the regulatory reform process. Such efforts are not new. In 1978, President Carter set out to reduce regulations, and similar efforts have been undertaken by every president since. EO 12866, signed by President Clinton in 1993, required that risk assessment be used to help evaluate the cost of new regulations, and if implemented whether they would improve the health and welfare of the American public. In this presentation, we discuss how these regulatory reform efforts have shaped today's use of risk-based decision-making for the management of environmental and human health policies and practices in the US.

**204 Cumulative risk analysis of contaminant mixtures in tap water: California case study**

*T.L. Stoiber, University of California-Davis; A. Temkin, S. Lunder, D. Andrews, O.V. Naidenko, Environmental Working Group*

Tap water in many communities in California has multiple contaminants at levels that meet national drinking water regulations, but are far from meeting public health goals for what scientists consider safe. National drinking water contaminant standards set under the Safe Drinking Water Act are a compromise between health benchmarks that define a minimal risk level on one side, and technical feasibility and cost of removal on the other side. Existing national and state regulations assess both drinking water standards and health benchmarks one chemical at a time, even though tap water nearly always contains a mix of contaminants. Systems with higher risk are often those that serve smaller, rural populations and drought conditions in California have exacerbated problems with common drinking water contaminants including disinfection byproducts and arsenic. Using California as a case study, we developed a cumulative risk approach for tap water contaminants conceptually similar to the other cumulative approaches developed for air pollution. We analyzed drinking water contaminant mixtures in tap water using the California state drinking water dataset for 2015 for most contaminants and the USEPA's Third Unregulated Contaminant Monitoring Rule (UCMR3) dataset for 2013-2015. Cumulative cancer risk estimates were derived by summing the cancer risk estimates for individual contaminants in tap water provided by individual water utilities. Contaminant co-occurrence analysis evaluated the simultaneous presence of contaminants with cancer and non-cancer health benchmarks. Based on the cancer potency and relative occurrence, cancer risk from tap water contaminants in California was primarily driven by the presence of arsenic, hexavalent chromium, and disinfection byproducts. Approximately 90 percent of the water systems had at least one contaminant at levels above health-based guidelines and approximately 63 percent had at least two contaminants above. Almost a quarter of the systems had four or more contaminants. Cumulative water contaminant analysis that accounts for the adverse health effects of co-occurring contaminants can identify water systems and communities most in need of resources for safe drinking water. Additionally, the health and economic benefits of reducing the levels of multiple contaminants with specific water treatment technologies should be considered when setting regulatory limits.

**205 Product Design as Institutional Work for Continuity and Change in Fields: Insights from a Study of Toxicogenomics for Ecological Risk Assessment**

*G. Pain, S. Maguire, McGill University / Desautels Faculty of Management; G. Hickey, M. Mondou, McGill University – Macdonald Campus / Dept Natural Resource Sciences; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences*

Much has been written about how toxicogenomics, i.e. collection and interpretation of information about gene and protein activity in cells in response to toxic substances, has the potential to make the assessment of chemical risks to health and environment cheaper, faster and more ethical as regards animal welfare. In part 1 of this paper, an analysis of the discourse of toxicogenomics reveals a fundamental tension: it is simultaneously constructed as just another tool in the risk assessment toolkit and as a revolutionary change heralding a transformative paradigm shift in toxicology. We compare the "tool" and "revolution" perspectives and identify key aspects of toxicogenomics where they diverge and this tension is most acute: envisioned uses; perceived barriers to adoption; interpretation of 'omics data; and approaches to validation. How do advocates of toxicogenomics navigate this tension? In part 2 of this paper, we address this question through a case study of a team of scientists (hereafter 'the product design team') undertaking the development of new quantitative PCR arrays (EcoToxChips) for characterization, prioritization, and management of environmental chemicals of concern. Because chemical risk assessment is an institutionalized field of professional practice, with methods and routines widely accepted and taken for granted, we examine changes in practices due to toxicogenomics through the lens of "institutional work," which is action taken to create, maintain and disrupt institutions. Drawing on qualitative data (scientific and regulatory texts; interviews and focus groups; participant observation of the product design team), we analyze the activities of the product design team, including interactions with regulators and other potential users of the EcoToxChip, as different forms of institutional work. By documenting key elements of prevailing, institutionalized practices and tracking their fate through the product design process, we show how some are maintained and reproduced, others are disrupted and abandoned, while new institutional elements are introduced by the EcoToxChip. We illustrate how, through the product design process, academic researchers' abstract, longer term "vision" of a transformative paradigm revolution is brought together and reconciled with regulators' concrete, shorter term "practical needs" for specific tools such that the new product affords both institutional continuity and change.

### 206 A Comprehensive Dispersant Hazard Assessment Based on Nearly 50-Years of Aquatic Toxicity Data

*A.C. Bejarano, Research Planning Inc. / Department of Environmental Health Sciences*

The use of dispersants as an oil spill response tool often causes concerns among the public and the scientific community because of their potential toxicity to aquatic organisms. The aquatic toxicity of dispersants has been extensively investigated under controlled laboratory exposures providing answers to scientific questions, while generating information applicable to a real-world issue and useful in addressing public concerns. Thus, mining these data would facilitate a boarder understanding of their toxicity, and enable a more comprehensive hazard assessment. Data from multiple studies were evaluated for their quality based on criteria allowing assessments of reliability. Although in recent years there has been an emphasis on the need of standardized aquatic toxicity testing, nearly a quarter of sources did not provide sufficient information on which to assess their quality. Between 1969 and 2018, over 100 aquatic species have been used in dispersant-only toxicity testing, with lethality (LC50) as the most commonly reported endpoint. The most extensively tested dispersants have been Corexit 9500 and Corexit 9527. The application of most of these data to real-world conditions is constrained by laboratory test conditions: data are primarily from constant static/static renewal tests under standard test durations (e.g., 96 h), which are not presentative of exposures under field conditions. However, data were used to develop dispersant-specific species sensitivity distributions (SSDs) and hazard concentrations protective of 95% of the species assemblage (HC5). Most of the 91 SSDs for 54 dispersants had HC5s falling within the moderate to slightly toxicity range. Data interpretation within the context of concentrations based on operational application rates indicated that HC5 exceedances may occur in the top few meters of the water column. However, under more realistic conditions, dispersant exposures would be short with concentrations rapidly declining below toxic levels. The goals of this presentation are to: 1) provide an overview of the body of scientific knowledge generated over several decades on the toxicity of dispersants; 2) offer recommendations on improved testing and reporting; 3) highlight possible research that is needed to translate data from standard tests into information that could inform decision making.

### 207 An avian reproduction study historical control database: A tool for data interpretation

*V.J. Kramer, Dow AgroSciences LLC / Ecotoxicology; J. Wheeler, Dow Agrosciences; P. Valverde-Garcia, Dow AgroSciences LLC; M. Foudoulakis, Dow AgroSciences LLC / RSRA ERS; T. Springer, EAG Laboratories / Specialist Projects & Histology*

Avian reproduction studies are a regulatory requirement for pesticides in many regions. The data often require careful interpretation due to the nature of the study design. Here we present the historical control dataset for bobwhite quail and mallard duck reproduction studies performed at the Evans Analytical Group LLC avian toxicology laboratory over the period 1985 – 2016. The analysis demonstrates the stability of reproductive parameters over time and good agreement to normal control ranges as required by the regulatory test guidelines. The major source of variation is shown to be within study variation. We believe the analysis and evaluation presented here can facilitate the development of practical guidance that can be implemented in regulatory programmes requiring this test. Data from 301 bobwhite quail and 292 mallard duck studies conducted between 1984 and May 2016 were colalted into an Excel spreadsheet. For mallard duck all birds were obtained from a single supplier or hatched at the laboratory from parents obtained from the same supplier. For bobwhite quail a total of 18 suppliers have been used. The data indicate that control response for both species has been stable over time (30+ years). Significantly, the means are in good agreement with the OECD guideline for normal (typical) values and the OSCPP guideline control responses for 'satisfactory' tests. The variation within a study (biological and experimental variation between replicates or pens) accounts for most of the variation of the historical control datasets for the different reproductive endpoints i.e. 64.9 – 93.4%. Between studies variation only explained a relatively small percentage of the total variance (5.7 – 35.1%). In the case of bobwhite quail, where the contribution to the total variance of the bird source (supplier) could be calculated, this factor accounted for an even smaller proportion (0.3 – 12.9%). These results indicate that the majority of the variation is from the intrinsic biological variability of the reproductive parameters and typical experimental variation. The power analyses show that greater replication would not dramatically increase the power properties for most endpoints. The HCD approach can therefore be useful to aid interpretation, improve regulatory decision making and minimise the need for repeat testing.

### 208 Actual and Perceived Risks in the Development of Water Management Strategies for Rural and Indigenous Communities

*M. Serville, Trent University / Environmental and Life Sciences; C.D. Metcalfe, Trent University / Water Quality Centre*

Members of rural and Indigenous communities may have concerns related to potential exposure to microbiological and chemical contaminants in their sources of drinking water. In order to develop a water management strategy that addresses these community concerns, it is important to understand the perceptions of risk among community members who are directly involved in the management of the water resources and communication of risks to the public. The perceptions of these professionals can influence the types or levels of risks they will tolerate, the compromises they make when implementing standards, and the strategies they put in place to manage and communicate risks. Further, multiple perceptions must be acknowledged and understood so that the water management sector can accommodate these points of view. In this study, a mixed-methods convergent parallel approach was used to assess actual risks from microbial and chemical contamination of drinking water for two rural communities located in mixed-use watersheds in Canada and the Caribbean, respectively. Actual risks were determined from quantitative data on the levels and sources of fecal bacteria, and concentrations of current use pesticides (CUPs) and chemical indicators of wastewater contamination in source water and treated drinking water using a hazard quotient (HQ) and hazard index (HI) approach. Perceived risks will be determined from qualitative data collected by interviewing water managers and health professionals within the communities. Quantitative and qualitative data will be integrated for an in-depth interpretation of how data on both actual and perceived risks can be applied to the development of water management strategies that foster effective risk communication, gain the trust of consumers and motivate consumers to respond positively. We anticipate that by translating scientific research into policy interventions, effective water management strategies can be developed.

# Linking Mechanism of Action to Physiological and Ecological Effects in Aquatic Species

### 209 Window of sensitivity to chemically induced alterations in gonad histology and reproductive function in largemouth bass (*Micropterus salmoides*)

*J.K. Leet, C.A. Richter, R.W. Gale, US Geological Survey / Columbia Environmental Research Center; J.A. Jenkins, USGS / National Wetlands Research Center; D.E. Tillitt, US Geological Survey / Columbia Environmental Research Center*

Field studies have shown a high prevalence of intersex in smallmouth bass (*Micropterus dolomieu*), and to a lesser extent largemouth bass (LMB; *Micropterus salmoides*), populations in the Chesapeake Bay watershed. The intersex phenotype has been correlated with the presence of the agricultural pesticide atrazine, which is widely used and one of the most commonly detected pesticides in the watershed. However, it is not known whether this intersex phenotype is associated with reduced reproductive function, which could lead to possible impacts at the population level. Adult LMB have been shown to be sensitive to induction of intersex in response to chronic exposure to a model estrogen (17alpha-ethinylestradiol; EE2) over a complete reproductive cycle. Late summer to fall is the period of early gonad recrudescence when spermatogenesis and oogenesis are beginning in preparation for the spawning season in the spring. Our objective was to assess whether early gonad recrudescence was a period of sensitivity for induction of intersex and/or alterations in reproductive function. Adult LMB were exposed in outdoor pond mesocosms from post-spawning through early gonad recrudescence to either EE2 (2.4 ng/L), or a mixture of endocrine-active substances commonly detected in the Chesapeake Bay watershed, atrazine (5.4 µg/L) and estrone (47.9 ng/L). Samples were collected from fish just prior to exposure (July), at the end of the exposure period (December), just prior to spawning (April), and post spawning (May). Endpoints at various levels of biological organization were evaluated, including: gene expression, plasma hormone concentrations, gonad stage, gonadosomatic index (GSI), liver somatic index (LSI), presence of testicular oocytes, sperm motility, number and volume of spawns, and 24 h embryo viability. Results indicated significantly lower GSI in pre-spawn females and males of the EE2 treatment and lower GSI in the mixture treatment females compared to the control. There was also a trend of lower sperm motility and egg volume in these treatments indicating potential reduced reproductive function. Of the individuals from the EE2 treatment that were externally identified as females just prior to spawning, two contained testes and one contained a testicular lobe and an ovarian lobe when examined at necropsy. This study presents evidence that early gonad recrudescence is a window of sensitivity for induction of intersex and potential reduction in reproductive function.

### 210 Is elevated organohalogen contaminant exposure linked to thyroid- and steroid-related gene responses in St. Lawrence beluga whales?

*A.E. Simond, UQAM / Biological Sciences; M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division; V. Lesage, Fisheries and Oceans Canada / Maurice Lamontagne Institute; R. Michaud, Group for Research and Education on Marine Mammals; J. Verreault, Université du Québec à Montréal / Sciences Biologiques*

Elevated concentrations of polychlorinated biphenyls (PCBs), chlorinated pesticides and halogenated flame retardants (polybrominated diphenyl ethers (PBDEs) and emerging compounds) have been reported in blubber of beluga (*Delphinapterus leucas*) from the St. Lawrence Estuary (Canada). It has been postulated that exposure to these contaminants might play a role in the non-recovery of this endangered population. In vitro and in vivo studies of mammals have shown that PCBs, PBDEs and chlorinated pesticides can perturb the homeostasis of circulating thyroid and steroid hormones or alter the expression of genes involved in their regulation. However, no study has yet investigated the linkages between concentrations of any contaminants in this vulnerable beluga population and impacts on endocrine axes. A suite of organohalogens (PCBs, chlorinated pesticides, PBDEs, and emerging flame retardants) was measured in blubber biopsy samples from 45 free-ranging male belugas from the St. Lawrence Estuary. Contaminant concentrations were related to the expression of gene transcripts measured in skin biopsy samples, and coding for nuclear receptors and proteins involved in the regulation of thyroid (*Dio1*, *Dio2*, *Thrα*, *Thrβ*) and steroid hormones (*Esrα*, *Hsd11β2*, *Hsd17β2*, *Nr3c1*, *Star*) as well as the metabolism of xenobiotics (*Ahr*). The four most abundant organohalogens in beluga blubber were in decreasing order $\Sigma_{37}$PCB, *p,p'*-DDE, $\Sigma_{29}$PBDE, and *trans*-nonachlor. $\Sigma_{37}$PCB, *p,p'*-DDE, *trans*-nonachlor and HCB concentrations were positively correlated with the transcription of *Dio2* and *Esrα*. Hexabromobenzene concentrations positively correlated with three steroid-related genes *Esrα*, *Hsd11β2* and *Nr3c1* as well as *Ahr*, while Dec-604 CB concentrations were negatively associated with the transcription of glucocorticoid and thyroid genes (*Hsd11β2*, *Nr3c1* and *Thrβ*). Results suggest that several biological functions including growth, development, reproduction, and energetic metabolism may represent potential targets for organohalogen exposure-related effects in this population. A suite of metabolites including amino acids, biogenic amines and fatty acids is currently being analyzed in skin of these belugas using metabolomics. Relationships between these markers, gene transcripts and levels of organohalogen compounds will be examined. Present study will contribute to better understand the health risks associated with elevated organohalogen exposure in endangered St. Lawrence Estuary belugas.

### 211 Connecting Developmental Thyroid Disruption to Impaired Reproductive Success in Fathead Minnows

*A. Johnson, P. Bruns, Texas Christian University / Department of Biology; M. Seemann, M. Hale, Texas Christian University; M.K. Sellin Jeffries, Texas Christian University / Department of Biology*

Thyroid disrupting compounds (TDCs) are known to interfere with normal thyroid hormone (TH) signaling. During embryonic and juvenile development, thyroid hormones modulate a variety of biological processes such as neurogenesis and the growth of the skeletal and muscular systems. Therefore, the majority of research on early life-stage (ELS) thyroid disruption has focused on its effects on growth and development. However, recent research has shown that ELS TDC exposure can also have adverse effects on reproduction later in life. Specifically, fathead minnows exposed to propylthiouracil (PTU), an anti-thyroid drug known to inhibit the synthesis of thyroxine (T4), during early development (from hatch through 42 days post hatch) experienced a 50% reduction in fecundity relative to controls. Interestingly, this statistically significant reduction in fecundity occurred when males, but not females, were subjected to ELS PTU exposures. After ruling out the possibility that ELS thyroid disruption altered testicular function, it was hypothesized that the observed reductions in fecundity resulted from changes in male reproductive behavior. To investigate the potential for and mechanism underlying PTU-induced alterations in male behavior, brains of PTU-exposed and control males were collected immediately after exposure for transcriptomic analysis. Of the genes that were found to be differentially expressed between the brains of PTU-exposed and control males, several were associated with sex steroid signaling. Specifically, PTU-exposed males experienced significant reductions in the expression of aromatase, estrogen receptor alpha, and androgen receptor, relative to controls. Given the known role of these genes in sexual differentiation of the male brain, these results provide evidence supporting the hypothesis that ELS chemically-induced hypothyroidism leads to altered brain development and subsequent alterations in behavior. Overall, the results of this study may help link transcriptomic alterations in the brain to alterations in reproductive behavior, which has important population-level consequences.

**212 Non-lethal sampling of the caudal fin and transcriptomics analyses enable marine diesel oil spill effects determination on Pacific salmon**

*J. Imbery, University of Victoria / Biochemistry and Microbiology; C. Buday, R.C. Miliano, Environment and Climate Change Canada / Pacific Environmental Science Center; D. Shang, Environment and Climate Change Canada / Pacific and Yukon Laboratory for Environmental Testing; J.M. Round, University of Victoria; H. Kwok, L. Purdey, Environment and Climate Change Canada / Pacific Environmental Science Centre; G.C. van Aggelen, Environment Canada / Pacific and Yukon Laboratory for Environmental Testing; C.C. Helbing, University of Victoria / Biochemistry & Microbiology*

Various types of crude and refined oils are involved in marine coastal spills and monitoring their impacts and the effectiveness of cleanup methods remains a challenge due to their highly complex and variable nature. Dispersion of soluble polycyclic aromatic hydrocarbons (PAHs) is influenced by water salinity and relatively little is known about their toxicity at typical salinities experienced in the Pacific Ocean (28-30 ppt). We investigated the PAH composition dispersed after a simulated marine low sulfur marine diesel (LSMD) spill and the utility of a non-invasive method of monitoring the impact on juvenile Coho salmon following a 96 hour exposure to low, medium, and high concentrations (100-1000 mg/L) of LSMD seawater accommodated fractions (LSMD-seaWAF). The sum of 50 known PAHs and alkylated-PAHs (TPAH-50) was measured using gas chromatography/triple quadrupole mass spectrometry daily. In contrast to lethal liver sampling for biological effects determination, the caudal fin is a readily accessible tissue which can be non-lethally sampled with minimal distress to the animal. Building on previous work, we investigated if the caudal fin transcriptome is an effective alternative to the liver to reflect the biological response of Coho salmon to LSMD-seaWAF. Our findings indicate that all LSMD-seaWAF preparations were saturated at ~30 ppb TPAH-50 and that the caudal fin *cyp1a1* gene transcript is a robust, non-sex-biased bioindicator of oil exposure exhibiting a 10-18-fold change in abundance from seawater control animals. RNA-seq analyses to more fully characterize the caudal fin response and identify additional impacted pathways is currently underway.

**213 Developmental and behavioral consequences of cannabinoid exposure in zebrafish**

*K.L. Willett, Z. Miller, D. Carty, J. Gledhill, C.E. Thornton, University of Mississippi / BioMolecular Sciences*

Due to relaxed prohibitions on cannabis use and therapeutic potential of cannabis constituents in the treatment of early-onset pharmaco-resistant epilepsy, exposure of children to these chemicals is increasing. Yet the consequences of developmental exposure to cannabinoids on the potential etiology of subsequent adult or multigenerational toxicity is currently unknown. The goal of this project is to study the toxicity of cannabidiol (CBD) and Δ9-tetrahydrocannabinol (THC) using zebrafish. Our central hypothesis is that developmental exposure to THC and/or CBD changes gene expression in critical genes during development that are, in turn, related to the origins of adult disease. To answer this question, F0 zebrafish were exposed via water from 6-96 hours post-fertilization (hpf) with either THC (0.08, 0.4, and 2 μM), CBD (0.02, 0.1, and 0.5 μM), or control (0.05% DMSO). RNA-seq analysis from 10 and 96 hpf fish revealed several genes that were differentially expressed compared to controls including metabolism (e.g. cyp1a, gstp1, nqo1) and solute carrier family genes (slc26a3.2 and slc51a). In addition to gene expression, larvae were also screened for abnormal development and behavior. Larvae exposed to CBD developed curved body axes, pericardial and yolk sac edemas, deflated swim bladders, and abnormal behavior. THC exposed larvae developed similar abnormalities, but at much higher concentrations than CBD. In order to assess reproductive fitness and latent adult disease, larvae were exposed to sub-LOAEL concentrations of CBD and THC for 96 hours then reared in untreated water. In F0s exposed to CBD and THC, fecundity was significantly decreased, but neither fertilization success nor F1 or F2 larval survival was adversely affected. An adult F0 open field behavioral test indicated a dose-dependent trend of increasing freezing duration after developmental exposure to CBD or THC which supports our hypothesis for cannabinoid related developmental neurotoxicity. This work highlights the need to consider long-term ramifications of early-life exposure to cannabinoids. Supported by the NIH NIDA (R21DA044473-01) and NIGMS (P20GM104932) and the UMMC Molecular and Genomics Core Facility.

**214 Contaminants of Emerging Concern in the Great Lakes: Effects from Simple Exposures to Complex Mixtures**

*U. Hasbay, S. Kohno, H.L. Schoenfuss, St. Cloud State University / Aquatic Toxicology Laboratory*

Contaminants of emerging concern (CEC), including pharmaceuticals, personal care products and industrial agents affect the health of aquatic organisms while there is a little information known about their inclusive harm to the ecosystem. Previous in vitro studies have documented that concentrated urban-sourced CEC mixtures hyper-stimulated fathead minnow ESR1 beyond the maximum induction of E2. Purpose of the current study was to form a bridge between long term, multigenerational studies conducted on complex mixtures of CECs, and understand the change on molecular and apical endpoints as the complexity of exposure increases. We tested the hypothesis that as the complexity of CECs in exposures increase, the molecular and apical endpoints observed will differentiate from simple exposure endpoints. We assessed the potential of 21 commonly detected CECs on two life stages of fathead minnows: juvenile (survival, escape performance, feeding efficiency, qPCR) and adult (survival, secondary sex characteristics, nest defense, courtship, boldness, plasma vitellogenin concentration, qPCR) after 96-hour flow-through exposures. In addition, we began the process of building a series of complex mixtures to study the CEC effects by using neural network methodology. Interestingly, exposure to ibuprofen showed an increase in body length at the medium concentration (environmental concentration) on larval fathead minnow ($p < 0.05$, ANOVA). We also observed indication of endocrine disruption on our mixture exposure which includes all studied chemicals. We expect that these evaluations will lead us to improve adverse outcome pathway concept by testing same chemical effects at different life stages of fathead minnows, and forming a linkage between behavioral responses and adverse outcomes.

**215 An AOP analysis of selective serotonin reuptake inhibitors (SSRIs) in fish with an emphasis on the cardiovascular and respiratory systems**

*M. McDonald, RSMAS, University of Miami / Marine Biology and Ecology; M.H. Amador, RSMAS, University of Miami*

Selective serotonin reuptake inhibitor (SSRI) antidepressants, such as fluoxetine, are found in measurable quantities in surface and ground waters. Because of their importance in human health, the pharmacokinetics and physiological impacts of SSRI treatment have been well-studied in small mammals and humans. There is also evolutionary conservation of the serotonergic system across vertebrates that, combined, allows for the read-across of known SSRI effects in mammals to potential SSRI impacts on aquatic organisms. Using an Adverse Outcome Pathway (AOP) framework, this presentation will examine the similarities and differences between the mammalian and teleost fish SSRI target, the serotonin transporter (SERT; SLC6A4), and the downstream impacts of elevated extracellular serotonin (5-HT; 5-hydroxytryptamine) – the consequence of SERT inhibition – on cardiovascular and respiratory organ function and on the response to low environmental oxygen levels (hypoxia) of teleost fish. Our data shows that fluoxetine treatment results in a decreased capacity to respond to hypoxia both on the cardiovascular level and on the level of metabolism and could suggest that waterborne fluoxetine exposure, especially when in combination with other SSRIs, may have a negative impact on fish survival when faced with the additional challenge of environmental hypoxia.

**216 Extension of the Human-Relevant Potency-Threshold approach to ecological species for hazard identification, AOPs, and cumulative risk assessment.**

*C. Borgert, Applied Pharmacology & Toxicology, Inc.; S.L. Levine, Monsanto Company / Global Regulatory Sciences*

The European Union has recently adopted Criteria and Guidelines for the identification of endocrine disrupting chemicals (EDCs), defined as chemicals that produce adverse effects via endocrine mechanisms. Identifying and characterizing toxic hazards based on the manner by which adverse effects are produced rather than on the nature of those adverse effects departs from traditional practice and requires a proper interpretation of the evidence regarding the chemical's ability to produce physiological effect(s) via a specific MoA. The ability of any chemical to produce a physiological effect depends on its pharmacokinetics and the potency by which it acts via the various MoAs that can lead to the particular effect. A chemical's potency for a specific MoA – its mechanistic potency – is determined by two properties: 1) its affinity for the functional components that comprise the MoA, i.e., its specific receptors, enzymes, transporters, transcriptional elements, etc., and 2) it's ability to alter the functional state of those components (activity). Recently an empirical approach was developed for determining the minimum level of mechanistic potency necessary for a chemical to be able to act via a particular MoA in humans, called the Human-Relevant Potency-Threshold (HRPT). Its application was illustrated through the development of an HRPT for the estrogen receptor alpha (ERα) agonist pathway of 1E-04 relative to the potency of the endogenous estrogenic hormone 17β-estradiol. The HRPT is useful for distinguishing between chemicals that may be capable of, versus those likely to be incapable of, producing adverse effects in humans via the specified MoA. This approach provides a practical means for addressing Hazard Identification according to the draft criteria for identification of EDCs recently proposed by the European Commission. Here, we show how the HRPT concept can be extended to analogous mechanistic thresholds in fish using comparative data for human and fish estrogen and androgen receptor systems. In addition, a practical method is proposed for using taxa-based potency thresholds for the identification of ecological hazards, as criteria for linking molecular initiating events to downstream key events in Adverse Outcome Pathways (AOPs), and for assigning chemicals to common assessment groups for mixtures risk assessment.

## Fate and Effects of Metals: Biogeochemical Perspective

**217 Understanding the role of DOM on mercury bioavailability – a prerequisite for the narrowing the gap in lab-to-field extrapolation**

*I. Worms, University of Geneva / Department FA Forel for Environmental and Aquatic Sciences; E. Moulin, University of Geneva; T. Chonova, N. Regier, V. Slaveykova, University of Geneva / Département FA Forel for Environmental and Aquatic Sciences*

Mercury biogeochemical cycle is strongly affected by the human activities, resulting in a significant increase of Hg compounds concentrations in the environment. What is more, Hg compounds bioconcentrate in biota, biomagnify along the food web and ultimately represent serious concern for the environmental and human health. However, mercury interaction with phytoplankton, central for its incorporation in the food webs, and in particular the role of dissolved organic matter (DOM) as bioavailability modifier is still to elucidate. The objective of this work is to get new insight in the role of the DOM on Hg bioavailability to phytoplankton. To this end, *C. reinhardtii* was exposed to Hg added to natural water rich in DOM from Onega Lake, Russia. Water was sampled from five sites representing the DOC gradient from River Shuya to open lake in March and June 2017. The water was spiked with 1 and 10nM of $Hg(NO_3)_2$ and let to equilibrate 1 or 24h, than the adsorbed and intracellular mercury concentrations in algae were determined after 2h exposure using direct mercury analyzer on freeze-dried algal pellets. Concentrations of Hg in the exposure media were measured with the MERX Automated Total Mercury Analytical System. In paralel the composition and the molar mass of the DOM was characterized by LC-OCD and flow-field flow fractionation – multidetection system. The amount of the SH- reactive groups was quantified too. Chemical speciation of Hg in the absence or presence of DOM was modelled. The results showed that adsorbed and intracellular Hg concentrations decreased as compared with exposure in the absence of DOM. No specific trends in the Hg uptake by *C. reinhardtii* were observed over DOC concentration gradients after 1h or 24h equilibration. However a clear decrease of the Hg bioavailability proportional to the aboundance of the reduced -SH groups was found. The principle component analysis showed that in addition to the abondance of the -SH groups of DOM, the other factors such as the presence and concentration of different nutrients, as well as mercury binding to the Al, Mn and Fe colloids has to be taken into account to understand Hg bioavailability to phytoplankton. The implications of the obtained results are discussed further with respect to the prediction of the mercury incorporation at the base of the food-webs and the narrowing the gap in lab-to-field extrapolation.

**218 Microbial activities versus mercury species reactivity in the deep sea sediment of the Capbreton Submarine Canyon (Biscay Bay, SW France)**

*A. Azaroff, CNRS / LCABIE-IPREM / Université de Pau / Biology and Chemistry; R. Guyoneaud, J. Deborde, C. Gassie, E. Tessier, IPREM CNRS UPPA; M. Monperrus, IPREM CNRS UPPA / Laboratoire de Chimie Analytique BioInorganique et Environnement LCABIE*

Due to its high affinity with particulate matter, mercury is readily scavenged from the water column and deposited to bottom sediment particularly in coastal and marine environments causing mercury contamination. In the sediment and under anaerobic conditions, mercury can be converted into monomethylmercury (MMHg), the most harmful form. The net production of MMHg results from both methylation and demethylation reactions mediated by both biotic and abiotic processes. In this work, relation between mercury levels (iHg and MMHg by ID-GC-ICP-MS) and microorganism taxonomic diversity (DNA 16s sequence by MiSEQ) were studied in deep sea surface sediment from the canyon of Capbreton in the Bay of Biscay. Twenty-four stations were investigated within the first 30 km of the canyon area in July 2017. Biogeochemical parameters (carbon content, grain–size distribution) were determined to characterize these samples. In parallel, study of mercury species transformations, from three stations selected according the distance to the coast, were performed in slurry incubations using mercury isotopic tracers under biotic and abiotic conditions. Mercury speciation analyses exhibited a wide range of IHg and MMHg levels from 18 to 972 and 0.150 to 2.11 $ng.g^{-1}$ dw, respectively. IHg and MMHg concentrations increased with depth and distance from the coast, whereas proportion of MMHg decreased along these gradients. Net methylation potentials were only observed under biotic conditions due to the involvement of prokaryotes in the transformation of Hg species. The determination of the taxonomic diversity and the sequencing of *hgcA* gene, a proxy for biotic methylation, have demonstrated the presence of two main families among the Deltaproteobacteria: *Desulfobulbaceae* and *Desulfobacteraceae*. These results reveal the involvement of these methylating strains in the MMHg production. Higher methylation potential was observed for the coastal stations whereas demethylation potential was similar for all stations, suggesting that environmental parameters (e.g. input of continental organic matter) also control methylating microbial activities. This work confirms the important role of the canyon to trap and transfer mercury via suspended matter from the continent to the abyssal plain and to be a reservoir for Hg and reactor for MMHg production mediated by anaerobic bacteria.

**219 Kinetics of Methylmercury Production in Contaminated Sediments**

*G. Schwartz, K. Muller, Oak Ridge National Laboratory / Environmental Sciences Division; T. Olsen, Geosyntec Consultants; S. Painter, S.C. Brooks, Oak Ridge National Laboratory / Environmental Sciences Division*

Mercury (Hg) is ubiquitous in the environment, occurring naturally and as an anthropogenic pollutant. In anaerobic environments, Hg can be transformed to methylmercury (MeHg), a neurotoxin that biomagnifies in the aquatic foodweb. The transformation of Hg to MeHg is a microbial process, mediated by a diverse group of anaerobic microorganisms. MeHg can also be demethylated, either through biotic processes or through abiotic reactions. The overall MeHg production in an ecosystem is the net balance of microbially-mediated Hg-methylation and both biotic and abiotic demethylation. Often researchers provide estimates of MeHg production levels in natural systems based on methylation and demethylation rates determined from laboratory experiments. Our previous work demonstrated MeHg production by periphyton biofilms harvested from East Fork Poplar Creek in Oak Ridge, TN. In these experiments, the data exhibited kinetics that were inconsistent with the first-order rate expressions typically used to analyze MeHg production data. We hypothesized that apparent non-first order kinetics in MeHg production were the result of competing kinetic reactions that reversibly converted Hg and MeHg to unavailable states. We used measurements of filter-passing Hg and MeHg, and a multisite adsorption model, to show that kinetic sorption reactions can lead to time-varying availability and non-first order kinetics in MeHg production. We constructed a new model to incorporate multi-site kinetic sorption. This model more accurately fit the range of behaviors seen in time course data for methylation and demethylation assays and resulted in much higher estimates of MeHg production than those predicted by single-rate, first-order models. Our current work applies this kinetic model to metabolically active transient storage zones within sediments from East Fork Poplar Creek. Experiments are underway to determine Hg and MeHg sorption and methylation/demethylation rates in the sediments. Sediments from different regions of the creek will be compared, and MeHg production rates will be correlated with measures of geochemistry and sediment microbial activity.

**220 Microbial generation of volatile mercury from dissolved methylmercury in seawater**

*C. Lee, N.S. Fisher, Stony Brook University / School of Marine and Atmospheric Sciences*

Elemental mercury ($Hg^0$) formation, followed by subsequent evasion from surface seawater, plays a principal role in the marine mercury cycle. However, the relative importance of microbial-mediated conversion of $Hg^0$ from Hg(II) or monomethylmercury (MeHg) in seawater remains unclear. A rapid radioassay method using the gamma-emitting $^{203}Hg$ as a tracer was developed to evaluate $Hg^0$ production by natural coastal bacterial assemblages for Hg concentrations in the low pM range. Bacterioplankton in Atlantic surface seawater collected 8 km off Long Island, New York, and in Long Island Sound water were found to produce $Hg^0$ from seawater containing Hg(II) and MeHg. $Hg^0$ gas evasion rate constants were independent of dissolved Hg(II) and MeHg concentrations and were directly related to bacterial biomass. About 32% of Hg(II) and 19% of MeHg were converted to $Hg^0$ in 4 d in Atlantic surface seawater containing low bacterial biomass, representative of coastal waters. In Long Island Sound water with higher bacterial biomass, 54% of Hg(II) and 8% of MeHg were transformed to $Hg^0$, inferring that bacterial community structures are important determinants for $Hg^0$ formation. Because low temperatures inhibited Hg(II) reduction substantially and bacterial mercuric reductase was detected in our samples, it can be further inferred that bacterial metabolic activities and enzymatic reactions govern $Hg^0$ formation. Decreasing temperatures from 24°C to 4°C reduced $Hg^0$ production rates cell$^{-1}$ from Hg(II) 3.3 times as much as from a MeHg source. Overall, these findings demonstrate the importance of $Hg^0$ formation mediated by naturally occurring marine bacterioplankton.

**221 Bioaccumulation and Translocation Efficiency of Metals in *Spinacea oleraceae* and *Celosia argente*a Grown on Olusosun Dumpsite Soil, Lagos Nigeria**

*O. Olojuola, A. Ogunyebi, University of Lagos, Akoka / Department of Cell Biology and Genetics; K.O. Omoyajowo, University of Lagos, Akoka / Cell Biology and Genetics / Environmental Biology*

The primary aim of this study is to determine the bioaccumulation factor (BAF) and translocation factor (TF) of heavy metals in two vegetables (*Spinacea oleraceae* and *Celosia argentea*) grown on soils collected from Olusosun dumpsite and that of University of Lagos biological garden (control). Planting of these two plant species was achieved within 4 weeks and harvested following standard analytical procedures. Result shows that metallic concentrations were significantly higher in both species of vegetable samples grown on Olusosun dumpsite soil in comparison to the control. Values for Zn, Cu and Ni were within FAO/WHO recommended level except for Pb (2.20-3.00 mg/kg) and Cr (0.62-1.98 mg/kg) in Olusosun dumpsite that had values above the FAO/WHO recommended limit of 2.0 mg/kg and 0.3 mg/kg respectively. In both vegetable species grown on soil samples collected from both sites (A and B) of Olusosun dumpsite, BAF values for Zn (0.124-0.154), Cu (0.07-0.096), Cr (0.025-0.034), Pb (0.023-0.029) and Ni (0.001-0.036) were less than one (1) showing that these plants only absorb heavy metals but did not accumulate them. Translocation factor (TF) was lesser than 1 in both plant species, and thus follow an order of Zn>Pb>Ni>Cu>Cr in *Celosia argentia* and Zn>Cu>Cr>Pb>Ni for *Spinacea oleracea*. Based on Sutherland classification, site A of Olusosun dumpsite soil was in moderate enrichment category for Zn (2.31), Cu (3.95), Pb (2.50) while site B of Olusosun dumpsite soil was in minimal enrichment category for Zn (1.50), Cu (1.29) and Pb (1.50). The study concluded that the use of dumpsite soil for growing vegetables has increased the concentration of heavy metals (Pb, Cu, Zn, Ni, Cd, and Cr) in their different parts and may pose a potential threat to human health in the long-term term.

**222 Metals removal from water for hazard classification**

*G. Burton, University of Michigan / School for Environment and Sustainability; M. Hudson, University of Michigan / School of Natural Resources and Environment; R.F. Carbonaro, Mutch Associates, LLC / Civil and Environmental Engr; K.J. Rader, Mutch Associates, LLC; S. Baken, European Copper Institute; P. Huntsman, Natural Resources Canada; E.R. Garman, NiPERA*

Metals usually enter aquatic ecosystems in an oxic environment and associated with particles. It is important to understand this initial fate process in regards to partitioning, speciation and resulting biological effects. In addition, current European Union regulations and the global GHS system mandate a hazard evaluation, which includes the assessment of Rapid Degradation (greater than 70% within 28 days).. A research program investigated the support for metal removal, partitioning, and transformation as a surrogate for rapid degradation for metals, through the examination of laboratory, field, and modeling data. A series of laboratory and modeling evaluations were conducted to address the following questions: Are metals, such as copper (Cu) and nickel (Ni), removed from the water column of freshwater systems and if so, what is the rate of removal? Can existing standard methods, like Transformation/Dissolution OECD 29 and OECD 308 be used or extended to measure metal removal? How do various test method conditions affect metal removal? What sediment substrates characteristics affect metal removal? Multiple dried vs. non-dried sediments were tested in batch reactors for 96 h and 28 d. Buffalo River, a standardized substrate , typically removed 70% Cu and Ni from the water column at 1 mg/L loading. Incubated sediments removed metals significantly faster than non-incubated sediments ($p < 0.03$). Higher sediment loading rates removed metals faster as expected. Sediment type and loading rates affected pH, which started at 6.0. Cu removal (96 h) and resuspension (1 h post 96 h) resulted in no significant increase in Cu. Removal rates of various metals could be reasonably predicted with modeling based on mechanistic processes. Results show 70% of Ni and Cu are removed from the water column using this OECD 29 – Extension test method, using a variety of sediments and conditions. These data can be used in a weight of evidence to demonstrate that metal rapid removal from the water column is occurring in natural systems.

**223 Metal removal from the water column for chronic hazard classification: Method development for an extended transformation/ dissolution protocol**

*P. Huntsman, R. Beaudoin, Natural Resources Canada / CanmetMINING; K.J. Rader, R.F. Carbonaro, Mutch Associates, LLC; M. Hudson, University of Michigan / School of Natural Resources and Environment; G. Burton, University of Michigan / School for Environment and Sustainability; S. Baken, European Copper Institute; E. Garman, NiPERA, Inc.*

The UN GHS and the EU Classification, Labelling and Packaging (CLP) hazard classification schemes include the concept of degradation whereby rapid degradation from the water column results in different classification cut-off values and categories. For metals and metal compounds, the assessment of environmental transformation may be taken into account. It was evaluated if an extension of the transformation/dissolution protocol (T/DP) could be used for assessing the rapid removal of metals from the water column. To this end, the T/DP method was extended with 2 parts: T/DP-E Part 1, to measure binding of metals to a substrate and subsequent settling and T/DP-E Part 2, to assess the remobilization of metals following resuspension of substrate. The aim was to provide a standardized approach to assess binding to substrate through sorption and metal speciation changes and subsequent settling of the non-soluble particles, and the likelihood for remobilization of metals. This presentation outlines the method development and the rationale for each critical point in the methodology. Three substrates were selected to represent a low binding (LBS), high binding (HBS) and a substrate of intermediate composition based on the Fe and total organic carbon (TOC) concentrations as both are important factors in metal partitioning from the water column. 10 g/L of substrate was added to pH 6 aqueous medium containing 1 mg/L of the metal of interest. The substrate loading was based on calculations of the settling flux of solids to the sediment in a typical lake environment. The 1 mg/L metal loading was selected as it is equivalent to the highest loading for chronic classification. pH 6 was selected as it is typically a worst case for metal dissolution. 96 h experiments were conducted using the LBS and T/D solutions containing dissolved Ni, Co, Cu, Pb, Zn and 0.1 mg/L Ag. Results indicate that >70% removal is achieved for Cu, Pb and Ag within 96 h. 28 day tests with resuspension were conducted tracking dissolved and total Cu and Sr with additional measurements for Fe as a fingerprint of the substrate. 95% of Cu and 41% of Sr was removed within 28 days with no measurable increase on resuspension whereas both total and dissolved Fe increase at the resuspension event. An assessment of experimental repeatability indicates that the results obtained are reproducible.

**224 Modeling Metal Rapid Removal Experiments for Hazard Classification**

*K.J. Rader, C. Fanelli, Mutch Associates, LLC; P. Huntsman, CanmetMINING, Natural Resources Canada; G. Burton, University of Michigan / School for Environment and Sustainability; D. Costello, Kent State University / Biological Sciences; S. Baken, European Copper Institute; E.R. Garman, NiPERA; R.F. Carbonaro, Mutch Associates, LLC*

In the context of hazard classification, the concept of degradability is an important consideration. For example, in the United Nations Globally Harmonized System (GHS) and European Union regulation on classification, labelling and packaging of substances and mixtures (CLP), less severe chronic classification entries are assigned to substances that are rapidly degraded (e.g. 70% degradation in 28 days). For metals, the concept of degradation as applied to organic chemicals has limited or no meaning. Recently, metal removal from the water column through partitioning/sedimentation and sequestration in sediment where proposed as a surrogate for degradation. A weight-of-evidence (WoE) approach was developed for assessment of metal removal from the water column. This approach relies upon an experimental component which is based upon existing standard methods OECD 29 (transformation/dissolution protocol) and OECD 308. The objective of the model development effort presented here is to provide mechanistic insight into important processes controlling removal from water column during the experiments performed using the OECD 29 and OECD 308 methods. A time-variable numerical model was developed in R using an explicit ordinary differential equation solver. The model was applied to datasets for copper, cobalt, strontium, silver, nickel, lead, and zinc. The OECD 29 and OECD 308 experimental data were successfully modeled with either a 2-layer (OECD 29) model or a 20-layer model (OECD 308). For the OECD 29 method, data for the various metals was described using a single (i.e., global) settling velocity, a single bulk exchange coefficient, and metal-specific kinetic adsorption rate constants and solid-solution distribution coefficients. The modeling analysis revealed that the important physical/chemical processes are kinetic adsorption of dissolved metals to particles, settling of particles and associated metals, and dissolved metal transport to and direct adsorption by the settled particles. For the OECD 308 protocol, metal transport via diffusion through bedded sediment layers played an important role in the loss of metal from the water column.

## Coupling Models with Monitoring Data and Future Perspectives for Exposure Assessment

**225 A Retrospective Review of Isocyanate Concentrations in Air and QC Samples from 3M Facilities Over the Last 6 years Using the ASSET EZ4-NCO Dry Sampler**

*C. Jacoby, 3M Company / 3M EHS Lab*

As a global company, the 3M Environmental, Health, and Safety; EHS Laboratory is called upon to analyze both personnel and work area samples to determine the airborne isocyanate concentrations in many of our facilities throughout the world. Using the ASSET EZ4-NCO Dry Sampler, we have developed an approach to ensure sample and data quality integrity throughout the entire sample collection, storage, shipping and analytical process. This approach allows us to evaluate sample stability and integrity during the entire process, and assign analytical uncertainties to each sample value reported, reflective of the holistic process. This presentation will discuss the 3M EHS Laboratory approach to this entire sampling process, focusing on the Quality Control aspects, from initial request to delivery of the final report. A retrospective evaluation of the analytical recoveries from the ASSET EZ4-NCO Dry Sampler for 2,4-toluene diisocyanate (2,4-TDI), 2,6-toluene diisocyanate (2,6-TDI), and 4,4'-methylene diphenyl diisocyanate (4,4'-MDI) from all relevant Quality Control samples over a 6-year period will be presented. Over this 6-year period, the average analytical recoveries (n, standard deviation) of 2,4-TDI, 2,6-TDI and 4,4'-MDI are 108% (176, 12.9%), 104% (167, 13.1%) and 104% (212, 13.0%), respectively. In addition to the above results, the analytical recovery of the dibutylamine derivatives of these three isocyanates from ASSET EZ4-NCO Dry Samplers stored over a period of several months will be presented. The application of the analytical recovery from all Quality Control samples to assign an analytical uncertainty to all sample final results will be discussed, with examples given.

**226 Bayesian uncertainties analysis of modelled chemical exposure of global fish community: How can ChemTHEATRE improve the performance of FATE?**

*I.C. Handoh, Niigata University / Graduate School of Science and Technology; T. Kawai, National Institute for Environmental Studies / Center for Health and Environmental Risk Research; T. Isobe, National Institute for Environmental Studies / Center for Environmental Health Sciences; N. Ohno, University of Hyogo / Graduate School of Simulation Studies; S. Uno, Kagoshima University / Faculty of Fisheries; T. Kunisue, K. Nakayama, Ehime University / Center for Marine Environmental Studies*

Numerical models such as Finely-Advanced Transboundary Environmental model (FATE) allow us to predict exposure of various environmental media (including atmosphere, oceans, soils, and biota) to chemicals, on a variety of spatiotemporal scales. However, there appear to be significant uncertainties in the model predictions, owing to those in the model input data and associated model parameterisations. Environmental monitoring datasets, against which the models are validated, have been largely limited in quantity and coverage, hence much effort is being devoted to data curation. Using a dataset curated on open-data platform ChemTHEATRE ('Chemicals' in the Tractable and Heuristic E-Archive for Traceability and Responsible-care Engagement), we evaluated the performance of FATE through a Bayesian uncertainties analysis in the light of uncertainties in the modelled exposure of global fish community to polychlorinated biphenyls (PCBs). Selected modelled processes to be discussed for this meeting are bioaccumulations in an Asia-Pacific ecosystem in the oceans, and exposure of sedimentary interfaces to PCBs, to improve model parameterisations and to better understand deep-sea mechanism that governs the fate and transport of PCBs, respectively.

**227 Evaluating the ability of probabilistic exposure models to predict sewage treatment plant effluent concentrations of chemicals disposed down the drain**

*J. Menzies, K. Casteel, The Procter & Gamble Co. / Environmental Stewardship and Sustainability Organization; K. Wehmeyer, P&G / Trace Analytical Core; K. McDonough, P&G / Environmental Stewardship*

Recent research has provided a better understanding of key parameters used in modelling the fate of consumer product ingredients disposed down the drain in the United States (US) including distributions describing per capita water use and sewer transit time. These distributions can be combined with laboratory based sewer and wastewater treatment plant (WWTP) simulation study results to create a high tier probabilistic model that predicts exposure concentrations in US WWTP effluents. The predicted concentrations can be compared with measured US WWTP effluent data in order to evaluate the strength of the model to predict actual environmental concentrations. Recent monitoring campaigns measured ingredient levels in the effluents of 40+ WWTPS across the US receiving >90% domestic wastewater. These domestic plants are expected to treat wastewater with the highest levels of consumer product ingredients. Case studies will include diethyldiester dimethyl ammonium chloride (DEEDMAC), amine oxide (AO) and linear alkyl benzene sulfonate (LAS). Recent effluent monitoring data will be compared with predicted effluent concentrations based on laboratory simulation studies in order to evaluate the ability of the model to predict actual environmental concentrations. In addition, this talk will discuss reasons for disparity between measured and monitored data and how to utilize all the information in a high tier exposure assessment.

**228 Pesticide surface water monitoring and ecohydrologic modeling to refine aquatic receptor exposure characterization.**

*P. Janney, J.J. Jenkins, Oregon State University / Environmental and Molecular Toxicology*

Pesticide surface water concentrations can be highly variable due to variation in climatic conditions, pesticide use associated agronomic practices, watershed geophysical and ecohydrologic characteristics. Pesticide surface water loading is a result of these stochastic processes leading to a range in concentrations that can vary on an hourly to seasonal time scale. Pesticide surface water monitoring is a deterministic approach to characterizing the stochasicity in pesticide surface water concentrations. Grab sampling provides point measures of exposure without an understanding of the temporal trends in exposure at toxicologically relevant time steps. Continuous sampling techniques, including passive sampling, can be useful in characterizing exposure on chronic time scales, however the variability of exposure concentrations on the acute time scale are normalized. Watershed scale ecohydrolgic models, including the Soil and Water Assessment Tool (SWAT), can be used to evaluate the connection between land management practices and pesticide surface water loading and assess pesticide surface water concentrations at appropriate time steps for exposure characterization. A modeling and monitoring approach was used to evaluate pesticide exposure in the Zollner Creek watershed located in the Willamette River Basin, Oregon. The Zollner Creek watershed contains designated critical habitat for two ESA listed Pacific salmonid species and has been intensively monitored since the early 1990s. SWAT model parameterization was based on realistic agronomic practices utilizing local expertise and probabilistic methods to characterize the spatial and temporal distribution of pesticide application practices. The probabilistic approach generated daily distributions of possible concentrations based on the characterization of the pesticide use practices. The daily distributions were evaluated to identify the most likely concentrations. The most likely concentration on a daily times step estimated by SWAT were compared with available grab sampling and passive sampling monitoring data to evaluate model performance. SWAT estimated daily data was also used to assess likely aquatic receptor pesticide exposure at acute and chronic time steps in relation to realistic pesticide application practices.

**229 Towards the development of a framework for applying non-target chemical analysis data within exposure and risk assessment**

*T. Gouin, TG Environmental Research / Safety and Environmental Assurance Centre; R. Parmar, ARC Arnot Research Consulting; J.A. Arnot, ARC Arnot Research & Consulting / Department of Physical & Environmental Science/Department of Pharmacology and Toxicology*

There is an increasing trend towards multi-targeted analysis and non-target screening methods to increase the number of analytes monitored in biomonitoring and environmental samples. While the opportunities from advances in chemical analytical capabilities have shown substantive development over recent years, application of information related to data reported from non-target analysis represents a challenge to the field of exposure modelling. For instance, there is no framework for interpreting and using data reported from studies involving non-target analysis to inform exposure and risk. The absence of guidance may consequently lead to difficulties in prioritizing substances for risk assessment or application in exposure estimation. In this study we examine the state of the science with respect to non-target analysis, and present a summary of the merits and limitations in risk prioritization and application in exposure assessment. These preliminary observations are then used to propose an initial framework for the appropriate use of non-target analysis data within exposure assessment. The recommendations concludes with a number of suggestions regarding how these data can be better gathered and reported in order to strengthen their applications for chemical risk assessment, including emerging contaminants.

**230 Elucidating the dominant pathways of human exposure to chemicals used indoors**

*L. Li, University of Toronto at Scarborough / Department of Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting / Department of Physical & Environmental Science/Department of Pharmacology and Toxicology; F. Wania, University of Toronto at Scarborough / Physical and Environmental Sciences*

The general population is exposed to a variety of chemicals used indoors such as plasticizers and flame retardants. Once released into the indoor environment, these chemicals can be taken up by humans via inhalation, dermal permeation or hand-to-mouth contact (non-dietary ingestion) resulting in "near-field" human exposure. Some of these chemicals are also able to migrate to urban and rural areas and enter human food chains; consumption of contaminated food then leads to "far-field" human exposure. In the context of multi-pathway exposure, identifying the dominant exposure pathway(s) is essential for minimizing human exposure and potential adverse effects. In this work, we investigate the relative importance of near- and far-field exposure routes of chemicals used indoors, using a human exposure model that incorporates multimedia chemical fate in the indoor-urban-rural continuum and bioaccumulation along terrestrial and aquatic food chains. The model is applied to simulate exposure of Swedish and Canadian populations to sets of hypothetical chemicals with different partitioning properties, persistence in environmental matrices, and biotransformation rates in organisms. All chemicals are assumed to be used and released entirely indoors. We find that, despite being released indoors, exposure to persistent chemicals with a log $K_{OW}$ between 6 and 11 and a log $K_{OA} > 6$ (e.g., higher substituted polychlorinated biphenyls and polybrominated diphenyl ethers) tends to occur primarily by dietary ingestion, whereas exposure to chemicals with a log $K_{OA} < 6$ (e.g., cyclic volatile methylsiloxanes) is likely to be dominated by inhalation of indoor air. If a compound can be readily degraded in the environment and within organisms, the contribution of dietary uptake decreases whereas that of indoor inhalation and non-dietary ingestion increases. Compared with Swedes, Canadians consume more terrestrial food (e.g., beef and dairy), thus the dietary contribution to their total exposure to chemicals with a log $K_{OA} > 6$ and a log $K_{OW}$ between 2 and 6 (e.g., phthalates) is relatively higher. This work, for the first time, provides a systematic overview of pathway-specific contributions to aggregate human exposure to the universe of chemicals used indoors.

**231 Responses of Mercury Deposition and Bioaccumulation in the Great Lakes Region to Policy and Other Large-scale Drivers of Emissions**

*J.A. Perlinger, N.R. Urban, Michigan Technological University / Civil and Environmental Engineering; A. Giang, University of British Columbia / Institute for Resources, Environment and Sustainability and Department of Mechanical Engineering; N.E. Selin, Massachusetts Institute of Technology / Institute for Data, Systems, and Society and Department of Earth, Atmospheric and Planetary Sciences; A.N. Hendricks, Michigan Technological University / Civil and Environmental Engineering; H. Zhang, University of Iowa / Center for Global and Regional Environmental Research; A. Kumar, S. Wu, Michigan Technological University / Geological and Mining Engineering and Science Department; V. Gagnon, H.S. Gorman, Michigan Technological University / Social Sciences; E.S. Norman, Northwest Indian College / Native Environmental Science Department*

Anthropogenic emissions combined with long-range atmospheric transport and deposition have contributed to a state-wide fish consumption advisory for mercury (Hg) in Michigan as in 35 other states in the U.S. Of ~70 lakes in Michigan's Upper Peninsula (UP) where walleye Hg has been measured, nearly 80% had concentrations above 0.3 ppm, USEPA's criterion value. Mercury (Hg) emissions pose a global problem; however, neither emissions nor regulations are uniform world-wide, and hence the impacts of regulations are also likely to vary regionally. We report here an approach to model the effectiveness of regulations at different scales (local, regional, global) in reducing Hg deposition and fish Hg concentrations in the Laurentian Great Lakes (GL) region. The potential effects of global change on deposition are also modeled. We focus on one of the most vulnerable communities within the region, a tribe in Michigan's Upper Peninsula (UP) with a high fish consumption rate. For the GL region, elements of global change (climate, biomass burning, land use) are projected to have modest impacts (< 5% change from the year 2000 to 2050) on Hg deposition. For this region, our estimate of the effects of elimination of anthropogenic emissions is a 70% decrease in deposition, while our minimal regulation scenario increases emissions by 35%. Existing policies have the potential to reduce deposition by 20%, with most of the reduction attributable to U.S. policies. Local policies within the GL region show little effect, and global policy as embedded in the Minamata Convention is projected to decrease deposition by approximately 3%. Even within the GL region, effects of policy are not uniform; areas close to emission sources (Illinois, Indiana, Ohio, Pennsylvania) experience larger decreases in deposition than other areas including Michigan's UP. The UP landscape is highly sensitive to Hg deposition. Sensitivity to mercury is caused primarily by the region's abundant wetlands. None of the modeled policy scenarios are projected to reduce fish Hg concentrations to the target that would be safe for the local tribe. Regions like Michigan's UP that are highly sensitive to mercury deposition and that will see little reduction in deposition due to regulations require more aggressive policies to reduce emissions to achieve recovery. We highlight scientific uncertainties that continue to limit our ability to accurately predict fish Hg changes over time.

**232 Who in the world is most exposed to PCBs? Using models to identify highly exposed populations**

*F. Wania, University of Toronto at Scarborough / Physical and Environmental Sciences; E. Undeman, Stockholm University / Baltic Sea Centre; T.N. Brown, TNB Research / Department of Chemistry; M. McLachlan, Stockholm University / Environmental Science and Analytical Chemistry (ACES)*

Human subpopulations experience different exposure to persistent organic pollutants (POPs) because of differences in the structure of their food webs and the extent of environmental contamination. We quantified the time-variant exposure of different human populations around the world to one representative POP, namely the polychlorinated biphenyl (PCB) congener 153, based on a dynamic simulation of both global environmental fate (using the model BETR-Global) and human food chain bioaccumulation (using the model ACC-HUMAN). The approach identified subpopulations whose diets include a warm-blooded carnivore (such as the Inuit eating marine mammals) as experiencing the world's highest PCB-153 exposure, i.e. the very large biomagnification potential of their food web more than makes up for the remoteness of their living environment. The results that Inuit eating a traditional diet are most exposed to PCB-153 is in agreement with empirical observations, as concentrations comparable or greater than those measured in Inuit have only been measured in people living close to major PCB point sources, who have been subject to occupational exposure, or who have been poisoned. For subpopulations that do not eat warm-blooded carnivores, the proximity to sources of PCBs is more important than food web structure and environmental conditions for differentiating their exposure to PCBs. Indeed, a worldwide survey of concentrations in human breast milk identifies exclusively central and Eastern European countries as having elevated PCB concentrations, consistent with the intensity of PCB emissions in this region. Concentrations in breast milk in countries in tropical latitudes and the Southern hemispheric are generally much lower, again reflective of the global distribution of historical PCB emissions.

## Non-Targeted Analysis: Comparing ENTACT Results and Assessing Informatics Approaches

**233 Study Design and Initial Results for EPA's Non-Targeted Analysis Collaborative Trial (ENTACT)**

*E.M. Ulrich, J.R. Sobus, J. Grossman, A. Chao, USEPA / Office of Research and Development / National Exposure Research Laboratory; R. Singh, Oak Ridge Institute for Science Education at USEPA / Office of Research and Development / National Exposure Research Laboratory; A.D. McEachran, K. Mansouri, Oak Ridge Institute for Science Education at USEPA / Office of Research and Development / National Center for Computational Toxicology; S. Newton, USEPA / Office of Research and Development / National Exposure Research Laboratory; C. Grulke, A. Richard, A.J. Williams, USEPA / Office of Research and Development / National Center for Computational Toxicology*

Non-targeted analysis (NTA) is a relatively new technique that strives to identify as many compounds present in a sample as possible, providing mostly qualitative results. NTA is useful to fill knowledge gaps about the many environmental chemicals posing exposure potential. However, most NTA approaches are in their infancy, with variable quality control and poor understanding of the domain of applicability. EPA's Non-Targeted Analysis Collaborative Trial (ENTACT) is designed to address these challenges through a controlled study involving multiple laboratories using different approaches on identical known, but blinded, samples. This presentation will cover the study design for ENTACT, specific results from the EPA analyses, and preliminary results from other participating laboratories (30 total). ENTACT samples include 10 synthetic mixtures containing 95-365 chemicals each, 3 exposure-related media extracts (unaltered and fortified with a mixture), and single chemical standards. Participating laboratories were initially blinded to the contents of the samples. After submission of initial results, participants are unblinded to fully evaluate their performance and allow adjustments to their workflow to improve results. About half the participants have submitted results using a variety of chromatography and mass spectrometry (MS) platforms. EPA analyses with liquid chromatography (LC) time-of-flight MS detected 60% of spiked substances in the mixtures, with true positive rates reaching a maximum of 68% after unblinding. Reproducibility rates averaged 75% for compounds repeated in multiple mixtures. Across a broader range of participants, method comparison between gas chromatography (GC) and LC showed that of 1,269 unique substances in the mixtures, 195 were not detected by either method; 809 were detected by GC (378 only GC), and 801 were detected by LC (265 only LC). Statistical separation of the GC-only, LC-only, and non-detected substance sets (Kruskal-Wallace non-parametric test, $P < 0.05$) based on 8 physico-chemical properties (BP, MP, $K_{oa}$, $K_{oc}$, $K_{ow}$, Henry's Law, VP, and water solubility) predicted from the OPEn quantitative structure-activity Relationship Application (OPERA) suggests differences in chemical space coverage among the 3 sets. ENTACT is the first study of its kind to objectively evaluate the performance of NTA methods on a common set of chemicals, providing a benchmark for current methods, and revealing areas for improvement and development.

**234 Comprehensive, Non-Target Characterization of Environmental Exposome Samples Using GCxGC & High Resolution Time of Flight Mass Spectrometry**

*T. Richards, L. Fell, J.E. Binkley, LECO Corporation / Separation Science Applications*

Historically targeted analysis has been the primary route to evaluate complex environmental samples. This constrained testing, while effective has often missed emerging or unexpected compounds within samples. Recent improvements in detection and data processing capabilities of various systems have allowed scientists to more fully evaluate these same samples using non-targeted (NT) techniques. As a result, the EPA is currently conducting a multiple lab, multiple platform evaluation for non-targeted analysis methods in samples designed to mimic the environmental exposome. The project contains two initial phases, first a blinded study is conducted and reported. In phase two the individual standard component lists are provided and the evaluation revised as necessary. Each blind standard is reported to contain between 100-400 spiked analytes with potential for more due to contaminants, intra-sample degradation or reaction product formation. This presentation describes the systematic logic used for identification of the unknowns, its results and the lessons learned from the process as it applied to the first round of ten, blinded ENTACT samples for a single platform. The platform used was a comprehensive GCxGC gas chromatograph coupled with a high resolution accurate mass (HRAM) time of flight mass spectrometer (TOF-MS) in both electron ionization (EI) & chemical ionization (CI) modes. Deconvolved spectra were matched to existing commercial MS libraries and screened based on the peak's retention index value, molecular ion mass accuracy and fragment ion formula fidelity. Questions addressed will be : (i) what percentage of each sample was correctly identified, (ii) what instrumentation characteristics contributed most significantly to the identification and (iii) what impurities, reaction products and degradation products were identified.

**235 Comparison of different ionization sources in the detection of unknown compounds in environmental samples within the EPA ENTACT project**

*N. Quinete, Florida International University / Analytical Chemistry; B. Ng, Florida International University / Chemistry and Biochemistry; P.R. Gardinali, Florida International University / Chemistry & Biochemistry and SERC*

The development of non-target screening methods to assess environmental contaminants of emerging concern, which are not commonly monitored for, is of utmost importance especially when there is no previous knowledge on the identity of the source of pollution. The advances in the field of high-resolution mass spectrometry offers great sensitivity and resolution, which coupled to ultra-high performance liquid chromatography represents a powerful tool for the separation and detection of a very large number of organic contaminants. Nowadays, the most commonly used ionization sources in LC-MS/MS are electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI). Although ESI is the most applied technique for polar and higher molecular weight compounds, APCI has been shown some advantages over ESI, especially in the ionization of thermally stable polar and non-polar compounds. The ionization process associated with APCI is considered more efficient and energetic than ESI, where gas phase reactions may generate more fragment ions relative to the parent ion. Also, APCI is less susceptible to signal suppression and matrix interferences than ESI. For certain classes of compounds that are traditionally very difficult to ionize or tend to show low sensitivity in LC-MS/MS, APCI has provided increased sensitivity for these 'tough to ionize' compounds, being considered a complementary technique to ESI. APCI has been reported to be more sensitive than ESI for triazines, phenylurea herbicides, biphenols, polyaromatic hydrocarbons (PAHs) and organochlorine pesticides. In this study, we have compared ESI and APCI for the detection of unknown compounds in 10 spiked samples (mixtures) as part of the inter-laboratorial study ENTACT conducted by the Environmental Protection Agency (EPA). Preliminary blinded results, without extensive manual processing, have shown the detection of 7911 features in APCI and 6428 features on HESI, with 2399 features in common to both ionization techniques. Kendrick mass plots and van Krevelen diagrams suggest that APCI was able to detect more chlorinated compounds and compounds with higher H:C and N:C ratio than ESI. Unblinded results will better elucidate the real capability of the methods in non-targeted analysis. In addition, the different ionizations sources will be also compared in real environmental samples (water samples collected from South Florida) regarding the detection and identification of unknown compounds.

**236 An Overview of Performance of the USEPA's Non-Targeted Analysis Collaborative Trial (ENTACT) Using LC-QTOF-HRMS**

*M. Wang, ECL California Dept. of Toxic Substances Control / Enviromental Chemistry Laboratory; J. Kinyua, Public Health Institute; J. Park, California Environmental Protection Agency / Department of Toxic Substances Control*

USEPA's ENTACT project was designed to facilitate international collaboration and comparison of analysis protocols across laboratories in the non-targeted analysis, emerging paradigm of environmental pollutants monitoring. In early 2017 we received ENTACT samples composed of 10 standard mixtures and 6 fortified sample extracts of wrist band, human serum and house dust. Upon completion of instrumental and data analysis, we submitted final report in September 2017. Thereafter, we received the key file and compared our submitted results and provided the evaluation summary. The samples were analyzed in both positive and negative electrospray ionization (ESI) modes using Agilent 6500 LC-QTOF-HRMS. Molecular features were extracted from raw data using commercially available software (Agilent Masshunter Qual). Features were aligned and quality control parameters were set to filter the features by peak intensity and subtraction of laboratory blank backgrounds using Agilent Mass Profiler Professional. The validated features were screened against the MS Ready library provided by USEPA. Matching results were further evaluated and validated, with a combined evaluation of matching score, retention times and structures. For the evaluation, we assigned three levels of positive identification to the reported compounds: one star for only accurate mass, two stars for mass and formula, three stars for mass, formula and structure. Overall, 53-70% of the spiked compounds were reported at one and two stars level of identification, and 33-63% spiked compounds were reported for three stars level. We identified a wide range of compounds with very different physical and chemical properties. We also curated those compounds that were classified as non-reported, and LC amenability was identified as the major reason. We also build libraries (negative and positive) by combining our experimental data with input from the key files, and additional information from the EPA CompTox Chemistry Dashboard. In this presentation, the instrument analysis method, data work flow, the results evaluation, and limitations will be discussed. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

**237 Probability Assessment for Identification in Non-Targeted Environmental Research (PAINTER): A new workflow for pollutant annotation and prioritization**

*L. Ferguson, Duke University / Nicholas School of the Environment Department of Civil and Environmental Engineering; G.J. Getzinger, ETH Zurich / Department of Environmental Systems Science*

High-resolution accurate-mass mass spectrometry (HR/AM MS) is capable of comprehensive structural elucidation of numerous trace-level organic contaminants in the environment. However, comprehensive sample characterization is made difficult by inefficiencies in the annotation and prioritization of detected features and postulated structures based on tandem MS analysis. We have developed a holistic, non-targeted analysis workflow to address these challenges, which combines ultra-high resolution tandem mass spectrometry, cheminformatics, and computational mass spectrometry. We have assessed and validated this approach through analysis of formulated chemical mixtures and serum, dust, and silicone wristband extracts as part of the EPA ENTACT collaborative trial. Samples were analyzed using an Orbitrap Fusion Lumos tribrid tandem LC-HR/AM mass spectrometer in ESI and APCI/APPI modes, in both positive and negative polarity. After feature detection, componentization, and alignment, custom data processing scripts were deployed to pipe relevant feature data to computational mass spectrometry tools for molecular formula assignment based on isotope pattern and fragment spectrum decomposition (SIRIUS, formulas assigned to >90% of features), harmonized spectral library searching routines (library size: 23,000 unique compounds) and structure assignment from the PubChem (database size: 65 million compounds) compound repository (postulated structures returned for >80% of features) and automated tandem mass spectral annotation and scoring (MetFrag CL, MAGMa, CSI:FingerID, and CFM-ID). A novel machine learning-based approach was developed and deployed to provide probability-based compound identification assessment from in silico MS/MS predictions, compound metadata (patents, references, and sources), and presence in prioritized compound database lists. After rigorous data filtering, organic compounds in samples and mixtures were tentatively identified according to an expanded Schymanski confidence scale, representing classes of pharmaceuticals, transformation products, consumer chemicals, and industrial compounds. Overall, our results highlight the benefit of combining of state-of-the-art computational mass spectrometry tools with chemoinformatic approaches for increased efficiency and annotation rate in non-targeted analysis approaches.

**238 Improvement of Mass Accuracy to Sub-ppm via Putative Lock Mass Algorithm (PLMA)**

*S. Kutarna, University of Toronto; H. Peng, University of Saskatchewan / Department of Chemistry*

Non-targeted analysis (NTA) using high resolution mass spectrometry (HRMS) provides a promising strategy to screen unknown compounds in complicated environmental matrices. For HRMS-based NTA methods, mass accuracy is the one of the most critical parameters used for the identification of environmental compounds. Preliminary studies found that the mass shift of HRMS showed large variations (>5 ppm) across different runs, or even between different retention times in the same run. This variation in mass shift increases the false discovery rate for NTA. The present study was motivated by the discovery of ubiquitous background contaminants in samples analyzed by HPLC-HRMS, which were identified as fatty acids or humic acids, present in the mobile phase as impurities. An algorithm was proposed to search all ions in the MS1 spectra (100-800 m/z) by 0.001 bins across all retention times. The background contaminants which could be detected across all retention times were selected as potential lock masses. Then, curve fitting was iteratively conducted to identify the optimal function to simulate the mass shift across different mass ranges. The m/z values for all ions in the spectrum were calibrated by the established calibration curves. Using this Putative Lock Mass Algorithm (PLMA), the mass accuracy of an Orbitrap mass spectrometer was improved from >5 ppm to sub-ppm accuracy. The PLMA was then successfully applied to NTA with different instruments (Q-Exactive, Q-Exactive HF) and environmental matrices (i.e. drinking water, house dust, and sediments). This algorithm will have important and broad applications for NTA in future studies.

**239 An Integrated Approach for Bio-effect Prediction based on Non-targeted Chemical Analysis**

*N. Kumar, J. Crago, Texas Tech University / Environmental Toxicology The Institute of Environmental and Human Health (TIEHH)*

Contaminants of emerging concern (CEC) such as pharmaceuticals and personal care products (PPCPs), flame retardants, industrial chemicals, pesticides, and their transformed products are entering the environment. Therefore, the environmental risk assessment of complex chemical mixtures requires an integration of analytical toxicology, molecular toxicology, and bioinformatics. The goal of this study is to integrate information from non-targeted chemical analysis of water samples, predict target(s) for chemicals with bioinformatic tools such as curated (Comparative Toxicogenomic Database, CTD) and non-curated databases (Similarity Ensemble Approach, SEA), and confirm predicted adverse outcomes with molecular techniques. Water samples were collected from 4 locations of Lubbock Canyon Lake System, which is dominated by wastewater treatment plant (WWTP) effluent. For example, a non-targeted chemical analysis (UPLC-orbitrap) was performed, and 4,423 unique structures were identified with the METLIN database in a water sample which was collected at approx. 7 miles downstream of the WWTP discharge point. 84.81% of identified structures were found in the USEPA CompTox database. Among unique identified compounds; 244 compounds were present in ExpoCast and 215 compounds were present in Tox21 Screening Library. The fathead minnow acute toxicity data was available for 31 compounds. Chemical gene interactions were identified with the SEA and CTD databases and a pathway analysis was performed using gene ontology (http://geneontology.org/). The top three pathways were Gonadotropin-releasing hormone receptor pathway, angiogenesis, and neuronal signaling disruption. The zebrafish *(Danio rerio*) model will be used to confirm the predicted toxicity. This presentation will outline the spatial and temporal distribution of CECs and their adverse effect on aquatic organisms in the Lubbock Canyon Lake System. Additionally, a workflow from non-targeted chemical analysis to bio-effect prediction will be presented.

## Existing, Emerging and New Chemical Contaminants in Changing Polar Environments

**240 What can Arctic seabirds tell us about changing emission patterns of contaminants?**

*B. Braune, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; A.J. Gaston, Environment and Climate Change Canada / National Wildlife Research Centre; M.L. Mallory, Acadia University / Biology Department; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; K.L. Foster, Karen Foster Environmental Research*

Environmental chemical contaminants are a global problem, and their presence in the Arctic reflects the integrated distribution processes and the way the Arctic interacts with the rest of the world. By examining contaminant levels in wildlife such as seabirds, we can look for new contaminants in the Arctic. Sentinel wildlife species, such as seabirds, can also be used to determine whether existing chemical contaminants of concern are increasing or decreasing, and whether those trends are being impacted by changing weather and climate conditions. Eggs of thick-billed murres (*Uria lomvia*), northern fulmars (*Fulmarus glacialis*) and black-legged kittiwakes (*Rissa tridactyla*) breeding on Prince Leopold Island in Lancaster Sound in the Canadian Arctic have been monitored for environmental contaminants since 1975. Concentrations of most legacy organochlorines such as the polychlorinated biphenyls (PCBs) and dichlorodiphenyltrichloroethane (DDT) have declined dramatically in arctic seabird eggs over the past 40 years in response to national and international regulations or bans. Likewise, concentrations of polychorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) have also declined, as have polychlorinated napthalenes (PCNs). Brominated flame retardants, such as polybrominated diphenyl ethers (PBDEs), increased in eggs of thick-billed murres and northern fulmars between 1975 and 2003 after which time levels declined, likely reflecting the phase-out of certain technical PBDE-containing products. Concentrations of poly- and per-fluorinated alkyl substances (PFASs) in murre and fulmar eggs remained unchanged (e.g. perfluorooctane sulfonate – PFOS) or increased (e.g. perfluorinated carboxylates- PFCAs) for several decades but levels may now have started to decline. We examine the temporal trends of these contaminant groups in arctic seabird eggs in the context of emissions and initiatives to reduce those emissions, as well as the potential impact that climate change may have on those trends.

**241 Sources, bioaccumulation, and biomagnification of PFASs in the ringed seal foodweb of Lake Melville, Northern Labrador, Canada**

*D. Xiong, University of Toronto / Geography; I. Lehnherr, University of Toronto; A.O. De Silva, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Kirk, Environment and Climate Change Canada / Global Tox; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; E.M. Sunderland, Harvard University / School of Engineering and Applied Sciences; I. Borea, A. Gleason, Environment and Climate Change Canada; R. Laing, Nunatsiavut Government; M. Li, The University of British Columbia / School of Public Health; L. Pijogge, T. Sheldon, Nunatsiavut Government; C. Spencer, M. Williamson, Environment and Climate Change Canada*

Perfluoroalkyl substances (PFASs) are a class of synthetic organic compounds that are highly persistent in the environment and can cause adverse health effects (e.g., endocrine disruption, immunosuppression, and cancer) in humans and wildlife. PFASs can be transported to polar regions via atmospheric oxidation of volatile precursors and ocean circulation. Due to their hydrophobic, lipophobic, and hydrophilic properties, PFASs may bioaccumulate in protein-rich tissues of organisms and biomagnify in foodwebs of remote ecosystems. One such remote ecosystem is Lake Melville, an estuarine fjord in northern Labrador, Canada, that receives both freshwater inputs (e.g., from the lower Churchill River) and marine water from the Labrador Sea. This region is currently undergoing environmental changes including climate warming and reservoir creation for hydroelectric power development at Muskrat Falls on the lower Churchill River. Consequently, PFASs levels to the local ringed seal (Phoca hispida) foodweb may increase, posing potential health concerns for local indigenous people who rely on ringed seals, fish, and other traditional country foods for sustenance. The objectives of this research are to identify environmental sources of PFASs and assess their bioaccumulation and biomagnification throughout the Lake Melville foodweb. Seal samples were collected between 2013-2017 by hunters during local harvests. Lower foodweb and water samples were collected between 2014-2017. Samples of seal and fish muscle and liver, water, plankton, and invertebrates were chemically extracted then analyzed for PFAS concentrations using UPLC-MS/MS. Principal Component Analysis of PFASs concentrations in water samples was used to identify possible sources of PFASs to this region, with results suggesting that short-chain and long-chain PFASs in Lake Melville may come from different sources. Calculation of bioaccumulation factors (BAF) in zooplankton, invertebrates, fish, and ringed seals demonstrates that certain PFASs bioaccumulate in the local foodweb. Stable isotope ratios ($\delta$13C and $\delta$15N) of foodweb samples and trophic biomagnification factor (TMF) will be determined to assess biomagnification of PFASs in the ringed seal foodweb. This study is the first to investigate PFASs in the ringed seal foodweb in Labrador and will shed light upon whether the levels of PFASs in ringed seals and other biota are of potential concern for the health of Northern Indigenous people.

**242 Contaminant concentrations are related to climate and weather factors in the Hudson Bay: A cross-species comparison**

*A.D. Morris, R.J. Letcher, B. Braune, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; M. Gamberg, Gamberg Consulting; J. Chetelat, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; J. Stow, Government of Canada / Northern Contaminants Program*

Wildlife from the Hudson Bay Region of Canada typically have among the greatest concentrations of persistent organic pollutants (POPs) and mercury (total mercury = THg) in the Canadian Arctic, and may be experiencing exacerbated climate change at their relatively low latitude ranges. In the present study, relationships between contaminants and weather/climate variables were investigated in polar bears (*Ursus maritimus*) from southern and western Hudson Bay (SHB and WHB), thick-billed murre (TBMU; *Uria lomvia*) from Coats Island, and caribou (*Rangifer tarandus*) from a WHB regional herd. THg was assessed in all species while POPs, including a–hexachlorocyclohexane (a–HCH), *p,p′*-dichlorodiphenyltrichloroethane (*p,p′*-DDE), 2,2′,4,4′,5,5′-hexachlorobiphenyl (CB-153), 2,2′,4,4′-tetrabromodiphenyl ether (BDE-47) and perfluorooctane sulfonate (PFOS), were assessed in bears and TBMU. Data were compiled from the early 1990’s (WHB bears, TBMU) or mid-2000’s (caribou, SHB bears) up to 2015. Annual and seasonal climate/weather factors included air temperatures, wind speeds, air pressure, precipitation, ice conditions (break-up, freeze-up, ice-free days), and the Arctic and North Atlantic Oscillation Indices (AO and NAO respectively). General linear models (GLMs) showed that caribou THg concentrations increased with increasing NAO (annual and spring) and AO (spring), and with earlier sea-ice breakup. THg models for WHB bears and TBMU showed that concentrations decreased with increasing spring and/or winter wind speeds. a-HCH concentrations decreased with an increasing, 1-year time lagged AO (June) in TBMU, while the concentrations decreased with increasing ice-free days in polar bears. In TBMU and polar bears, *p,p’*-DDE increased with increasing air pressures or decreased with increasing precipitation. Concentrations of BDE-47 increased with increasing precipitation (annual) in TBMU, while decreasing with increasing winter precipitation in WHB bears. A 1-year lagged AO (fall) produced the best model for CB-153 in polar bears, while the lagged NAO (fall and summer) was most significant for TBMU (sea-ice conditions were also significant for both). PFOS decreased with increasing annual and spring land surface temperatures. Some similarities were evident; however there were both distinct and subtle differences in the relationships observed that suggest that climate change may differentially affect contaminant trends in these species.

**243 Evidence for microplastic contamination in remote Canadian Arctic archipelago marine sediments**

*J. Adams, University of Toronto / Earth Sciences; L. Jantunen, Environment and Climate Change Canada; M.L. Diamond, University of Toronto / Department of Earth Sciences; S.A. Finkelstein, C.M. Rochman, S. Bernstein, University of Toronto; G. Stern, Fisheries and Oceans Canada*

Plastics are an integral part of contemporary society. Researchers have estimated that 8300 million tonnes of plastic were manufactured by 2016, of which 6300 million tonnes have ended up as waste. Single-use sources, such as bags and packaging, are an important contribution to this waste. Plastic waste degrades or fragments to become microplastics, which are plastic particles of < 5 mm. Microplastics are a concern due to the threat posed to terrestrial and aquatic organisms when ingested, which may then be transferred through the food web to higher trophic levels. Evidence continues to emerge showing the ubiquitous distributions of microplastics in the environment, and there is limited but growing evidence showing their presence in remote Arctic environments. The presence and impact of microplastics in the Arctic may be exacerbated by climate change, through melting of multi-year sea ice releasing previously contained microplastics, and increased ship transportation in the Arctic. Our research aims to determine the extent of microplastic contamination across the Canadian Arctic archipelago marine system, and to evaluate sources and transport pathways of the microplastics. Fourteen surface sediment samples were collected between 2014 and 2017 across approximately 3,300 km of the Canadian Arctic archipelago marine system and from water column depths ranging from 40 to ~1500 m, as a part of ArcticNet. The surface sediments were examined for microplastic particles > 20 µm, specifically particle abundance, distribution and characteristics. Our data indicate the presence of microplastic particles in all 14 samples. However, abundance of particles varies across sites. In the size fraction > 500 µm, microplastic abundance varies by an order of magnitude (from 360 to 5,000 particles/kg dried sediment). The greatest abundance of microparticles > 500 µm was found in the western-most sample located in the Beaufort Sea just offshore of Alaska. The lowest abundance was found in a sample located in the eastern Canadian Arctic, in the Davis Strait just offshore Baffin Island. Particle types were mostly fibers, with fragments as the second most common particle type. Our results indicate the ubiquity of microplastics across the Canadian Arctic Ocean, and that microplastics likely undergo long-range transport in marine systems, but that there is also the potential for local sources even in remote environments.

**244 OCPs and PCBs in the terrestrial environment of Schirmacher Hills, Antarctica: Environmental assessment and degradation**

*A.K. Tiwari, NCAOR / Polar Environment; s. K L, IIT Hyderabad; A. Qureshi, IIT Hyderabad / Civil Engineering; P. Chakraborty, SRM University*

Antarctica has been historically considered a remote and pristine continent. However, long-range transport of pollutants from other continents, and local activities in research stations and the Antarctic tourism industry have introduced many contaminants in the region. In this work, we report the occurrence of organochlorine pesticides (OCPs) and polychlorinated biphenyls (PCBs) in mosses, soil and water from the Schirmacher Hills, Dronning Maud Land, Antarctica (latitude 70°43′50"S–70°46′40"S, longitude 11°22′40"E–11°54′25"E). This is the first study in the region after the ban on production and consumption of the legacy POPs. We present results on the occurrence of PCBs and OCPs in the terrestrial environment of Schirmacher Hills, Antarctica, and direct PCB release in the region, and the degradation kinetics of PCB congeners. Out of nine evaluated OCPs [α-hexachlorohexane (HCH), β-HCH, γ-HCH, δ-HCH, α-Endosulfan, β-Endosulfan, Endosulfan sulfate, *p,p′*-dichlorodiphenyldichloroethylene (DDE) and *p,p′*-dichlorodiphenyldichloroethane (DDD)], only α-HCH and *p,p′*-DDE were detected in moss. α-HCH concentrations (4.48 ng/g dw) were comparable to other locations while *p,p′*-DDE (31.2 ng/g dw) concentrations are higher than those observed by 5 times or more. None of the OCPs were detected in soil. Out of the tested 28 polychlorinated biphenyl (PCB) congeners, only 6 PCBs were detected. $\Sigma_{28}$PCBs in both moss (122 ± 115 ng/g dw, $n = 5$] and water (30 ng/L and 165 ng/L, $n = 2$) are higher by up to 10 times compared to other studies around the continent. Heavier congeners (hexa through nona) in both moss and water samples constitute 52–100% of $\Sigma_{28}$PCBs. This suggests that some localized sources of PCBs may still exist in the Schirmacher Hills region. It is possible that the old research stations in the area may be one of those sources. We find that while the observed congener distribution can be expained using congener distributions in known commercial PCB mixtures (Aroclors, Sovol and Clophen) in some samples, a post-depostition transformation in snow/ice (in glaciers) is required to explain the remaining observations.

**245 Interactions of persistent organic pollutants with vitamins A and E in the blubber of killer whales moving into Arctic waters**

*S. Pedro, University of Connecticut / Natural Resources and the Environment; R. Dietz, C. Sonne, Aarhus University / Department of Biosciences, Arctic Research Centre; A. Rosing-Asvid, Greenland Institute of Natural Resources; M. Hansen, Aarhus University / Department of Environmental Science; M.A. McKinney, McGill University / Department of Natural Resource Sciences*

Along with Arctic sea ice contracting both spatially and temporally, North Atlantic killer whales (*Orcinus orca*) appear to have expanded their habitat ranges into Arctic regions. In the Canadian Arctic and Greenland, killer whales have been observed hunting marine mammals, which may represent a shift from their presumably fish-based diet in North Atlantic waters. Consistent with this, we recently showed that 18 individuals sampled in Greenland from 2012-2014 appeared to have high blubber levels of biomagnifying persistent organic pollutants (POPs) [e.g. ΣPCB: 71.6 ± 18.4 mg $kg^{-1}$ lipid weight (lw)] relative to conspecifics stranded in the North Atlantic in 2008 (ΣPCB: 5.2 ± 1.7 mg $kg^{-1}$ lw). About 67% of the Greenland killer whales showed PCB levels exceeding threshold of effects of 41 mg $kg^{-1}$ lw reported for other marine mammals. To further examine the potential consequences of these high POP levels in the Greenland killer whales, we evaluated the levels of vitamins A and E in the blubber of a subset ($n = 15$) of these individuals and examined the relationship with POP levels. Due to lipid stratification that occurs within marine mammal blubber, we additionally compared levels of these lipophilic vitamins and POPs between the innermost and outermost layers of the blubber. Blubber levels of vitamin A (measured as retinol) averaged 32.8 ± 4.6 µg $g^{-1}$ wet weight (ww) ~72.9 ± 12.1 µg $g^{-1}$ lw, and levels of vitamin E (measured as α-tocopherol) averaged 34.1 ± 4.4 µg $g^{-1}$ ww ~75.0 ± 12.0 µg $g^{-1}$ lw. Preliminary results suggested similar levels of vitamin A between inner and outer blubber layers, while levels of vitamin E were significantly higher in inner compared to outer layers (both at lw and ww basis, $p < 0.001$). Moreover, levels of vitamin A were similar among sex/age classes, while ww levels of vitamin E were higher in adult females compared to subadults ($p = 0.01$), but similar at lw basis. After accounting for this variation related to blubber layer and sex/age class, as well as diet based on fatty acid signatures, we will perform an assessment of the relationship of blubber vitamin A and E levels to blubber POP levels. We will eventually use the results to estimate a toxicity reference value for vitamin A and E disruption in killer whales. Such value allows further refinement in the assessment of risks posed by POPs for these high trophic level marine predators, which may be critical as their exposures change due to entry into novel Arctic habitats.

**246 "New" PCBs in the Arctic: New surface snow measurements from Svalbard**

*M.H. Hermanson, Hermanson & Associates LLC / Environmental Chemistry; P. Bartlett, City University of New York; E. Isaksson, Norwegian Polar Institute; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division*

We contributed "New unintentionally generated PCBs in the Arctic" for the Arctic Monitoring Assessment Program's (AMAP) 2016 Assessment: Chemicals of Emerging Arctic Concern (CEAC), presenting some unresolved anomalies and the difficulty assessing the proportion of PCBs observed from long-range transport and local sources on Svalbard. Since then we have analyzed 209 PCB congeners in surface snows in four sites across Svalbard using EPA method 1668. Unintentionally produced PCB-11 is consistently measured in high proportions globally and more recently in polar observations. For AMAP we reported the Garmash et al. (2013) time line of ice core measurements from the Lomonosovfonna glacier on Svalbard from 1957-2009 with estimated PCB-11 fluxes of 0.18-0.45 pg $cm^{-2}$ $yr^{1}$. Surface snow samples showed a PCB-11 flux of 0.83 pg $cm^{-2}$ $yr^{1}$, 2009–2010. Variations in measurements over time and ice cores vs surface snow may arise from surface air exchange (volatilization) of the lower molecular mass and more volatile PCB congeners (mono's, di's and tri's) during summer. While most of the research has focused on the origin of PCB-11 and other unintentionally produced PCB from pigment, thermal sources are also a possible source. Surface snow samples were collected from four glaciers on Svalbard representing the winter of 2013-2014 at Austfonna, Holtedahlfonna, Kongsvegen and Lomonosovfonna. The sites are maximum 220 km apart west to east (Holtedahlfonna to Austfonna). PCB-11 is prominent in all of the samples. Kongsvegen is distinguished with the lowest flux of PCB-11 (0.50 pg $cm^{-2}$ $yr^{1}$), while the other three sites have nearly equal inputs of about 0.72 pg $cm^{-2}$ $yr^{1}$. EPA method 1668 enables us to distinguish PCB-5 from other congeners (PCB-8 for example), providing new questions about sources. We see PCB-5 in all samples, ranging from 1% – 3% of total PCB with an declining flux trend from west to east: Kongsvegen (0.71 pg $cm^{-2}$ $yr^{1}$), Holtedahlfonna, (0.60 pg $cm^{-2}$ $yr^{1}$), Lomonosovfonna, 0.32 pg $cm^{-2}$ $yr^{1}$, and at Austfonna, 0.11 pg $cm^{-2}$ $yr^{1}$, suggesting that PCB-5, and some other PCB congeners at western Svalbard sites may be from local sources. PCB-5 was not produced in Aroclor mixtures (USA, UK), or in Clophen (Germany). We are investigating the possibility that PCB-5 was found in the Russian product "Trichlorodiphenyl" (TCD).

**247 Organophosphate Esters Flame Retardants and Plasticizers in Arctic Waters**

*L. Jantunen, Environment and Climate Change Canada; S. Bernstein, University of Toronto; G. Stern, Fisheries and Oceans Canada; A. Burt, University of Manitoba*

Organophosphate ester (OPEs) flame retardants and plasticizers are receiving increased attention due to their high levels in indoor air and dust and presence in remote locations including the Canadian Arctic. The widespread global distribution of OPEs is believed to arrive through various mechanisms including oceanic transport and air transport in the gas phase and on fine particles that undergo disposition in the colder arctic environment. Water samples were collected throughout the Canadian Arctic between 2013-2017 as part of ArcticNet and the Northern Contaminants Program. Samples were mainly taken from on board the CCGS Amundsen but also at a land based station in Resolute Bay, NT and Daneborg, Greenland. Levels were very high compared to other flame retardants including PBDEs. OPEs most frequently detected in the arctic environment were tri-phenyl phosphate (TPhP), tris(2-chloroethyl) phosphate (TCEP), tris(2-chloroisopropyl) phosphate (TCPP) and tris(1,3-dichloro-2-propyl) phosphate (TDCPP). Some OPE compounds are becoming more frequently detected in arctic waters, this includes ethyl-hexyl diphenyl phosphate (EHDPP), tri-cresyl phosphate (TCP) and tris(2-isopropylphenyl) phosphate (T2iPPP). We found levels were lower on the eastern side of the Canadian archipelago and higher in the Beaufort Sea. Iso-propylated and tert-butyl diphenyl organophosphates were also found in the arctic environment. We will present spatial trends within the Canadian arctic as samples spanned a west to east transect from the Beaufort Sea to Baffin Bay and identify possible sources.

## Advancing Fate and Effects Modeling and Their Integration to Increase the Relevance and Robustness of Risk Assessments

**248 Identifying important drivers in exposure and effects mitigation assessments: A general global sensitivity and uncertainty analysis framework**

*R. Muñoz-Carpena, University of Florida / Agricultural & Biological Engineering; G. Fox, North Carolina State University / Agricultural and Biological Engineering; A. Ritter, Waterborne Environmental, Inc.; O. Perez-Ovilla, Bayer CropScience / Environmental Safety; I.M. Rodea-Palomares, Bayer CropScience LP / Environmental Toxicology & Risk Assessment*

Long-term environmental risk assessments (RA) involve the combination of complicated deterministic models to ascertain regulatory compliance. The modeling framework often involves large sets of input factors (model parameters, initial and boundary conditions, and other model structure options). How can we identify the relative importance of human, chemical, physical and biological drivers on the assessment results? Is there a case for "the right answers for the right reasons"? For the case of mitigation practices like vegetative filter strips (VFS) for runoff mitigation, what are the important factors controlling or limiting their field efficiency under different field settings? Global sensitivity and uncertainty analysis (GSUA) represents a powerful and flexible framework to evaluate the uncertainty of the assessments, the relative importance of the factors controlling the results, and their predominant contribution to the model output (direct effects, interactions, non-linearities, and directionality). We present the GSUA framework and its application to the case of runoff mitigation with VFS to test alternative hypothesis on the relative effects that different field conditions can have on the assessments with and without this field practice. We evaluate the combination of the current EPA RA in combination with VFSMOD, an established numerical model for the analysis of runoff, sediment, and pesticide transport in VFS. We present a systematic study of the importance of different field conditions that have been proposed in the past as limiting the efficiency of VFS in realistic settings: flow concentration (channelization) through the filter, timing of pesticide application compared to other drivers, assumptions about the pesticide degradation trapped in the filter between runoff events, and seasonal presence of a shallow water table near the water body. We identify instances in which the importance commonly assigned to these factors is not supported by the mechanistic analysis, where other factors different than those proposed largely control the results of the assessments.

**249 Sensitivity analysis for an integrated avian fate and effects model**

*M. Etterson, USEPA / ORD / NHEERL / Mid-Continent Ecology Division; N. Galic, Syngenta Crop Protection, LLC / Environmental Safety; J.P. Carbone, Knoell USA / Environmental Health and Safety; V. Kurker, USEPA / ORD / NHEERL / Mid-Continent Ecology Division*

Ecological risk assessment models integrate information on exposure, toxicity, and life history to predict potential risk to ecological receptors. However, the underlying biological and ecological processes occur at different temporal rates and are often measured at different levels of resolution. These considerations of scale and measurement resolution influence the importance of different parameters for conclusions about risk that can be illuminated using model sensitivity analysis. We present a thorough sensitivity analysis of the MCnest model for each of these three model parameter categories (life history, exposure, and toxicity). For toxicity we include two terrestrial exposure models, the Terrestrial Residue Exposure Model (T-REX) and the Terrestrial Investigation Model

(TIM), which operate at different levels of complexity. Among life history parameters, nest and adult survival rates are the most influential parameters determining seasonal productivity. Among exposure and toxicity parameters, application rates, water solubility, and degradation rates were the most important parameters. Different sensitivity metrics conveyed different information about the effects of perturbations in model parameters and were not necessarily correlated with each other. This highlights the importance of careful thought about what metric to choose to characterize model

**250 Coupled exposure-effect models for evaluating VFS efficacy to mitigate pesticide risk to aquatic ecosystems**

*I.M. Rodea-Palomares, Bayer CropScience LP / Environmental Toxicology & Risk Assessment; Q. Zhao, University of Florida / Agricultural and Biological Engienering; R. Muñoz-Carpena, University of Florida / Agricultural & Biological Engineering; A. Ritter, Waterborne Environmental, Inc.; G. Fox, North Carolina State University / Agricultural and Biological Engineering; E. Blancher, Moffatt & Nichol; D. Park, Eco Modeling, Diamondhead*

Environmental Risk Assessment (RA) of pesticides is based on the comparison of environmental exposure concentrations (EECs) with concentration thresholds that are considered protective of aquatic organisms based on laboratory toxicity testing. However, a better understanding of the implication of long-term pesticide exposure on aquatic ecosystems is missing. This understanding could be accomplished by linking exposure models and mechanistic aquatic effects models. Recent improvements in mechanistic aquatic effects models, like AQUATOX, allow for better estimates of the potential ecological effects of chemical pollutants on different food-web compartments at a daily resolution. Vegetative filter strips (VFS) models such as VFSMOD are used to simulate the influence of VFS and riparian buffers as a mitigation practice with demonstrated efficacy in reducing EECs in higher tier pesticide RA. However, the potential to predict the impact of these mitigations on aquatic organisms has yet to be studied in a coupled exposure-effects framework. In this research, we link EPA's long-term pesticide RA modeling framework (Pesticide in Water Calculator, PWC) with AQUATOX to evaluate the efficacy of VFS as a mitigation measure in order to reduce long term pesticide risk to freshwater organisms. EPA's agro-ecological scenario for Oregon-wheat with variable VFS lengths, from no VFS to 9 m, was selected at the margin of a representative river segment to simulate daily 30-yr runoff, sediment and pesticide loads at the river edge. The field loads together with daily hydrologic and climatic changes were used as daily inputs to AQUATOX parameterized as a river segment matching ecological characteristics of a representative salmonid river in Oregon. We estimated the effects of pesticide loads on the different ecosystem functional groups, and the potential VFS for mitigating observed pesticide effects over the 30-yr period. Relevant metrics describing exposure and effects are explored. Preliminary results indicate that VFS could be a useful mitigation measure to prevent pesticide-derived long-term effects on freshwater organisms, but that there is a non-linear translation from change in exposure to magnitude of effects based on the efficacy of VFS.

**251 Watershed modeling: Comparison of process-based model PRZM/SWAT with regression-based model SEAWAVE-QEX**

*W. Chen, Syngenta Crop Protection; D. Perkins, A. Jacobson, C. Roy, F. Abi-Akar, Waterborne Environmental Inc.*

Water quality monitoring data, specifically for pesticides, can represent best-available exposure profiles relevant to ecological risk assessment; however, there are challenges in synthesizing these data toward making conclusions about the nature of the potential range of risk. Some of these challenges include: data collection frequency, monitoring period duration, interpreting exposure profiles from one location to another, and monitoring system scale. To address these challenges, statistical approaches may be applied to characterize empirical trends. Additionally, process-based numerical modeling approaches can offer a different perspective on synthesis and interpretation of monitoring data. A comparison of a statistical and process-based numerical model was conducted to evaluate strengths and weaknesses of representing, synthesizing, and conclusions from monitoring data. This comparison was developed from pesticide measurements of six intensively-monitored HUC12 headwater watersheds in the Midwest. SEAWAVE-QEX is a regression model that incorporates a linear trend term, covariates accounting for seasonality, and a transformation of flow to represent a long-term pesticide trend at a specific monitoring location. PRZM/SWAT (Pesticide Root Zone Model/Soil Water Assessment Tool) is a spatially-distributed hydrologic and chemical transport numerical model that combines upland chemical and hydrologic processes from PRZM and stream flow and chemical transport processes from SWAT. The predictive quality and limitations of these two models (SEAWAVE-QEX and PRZM/SWAT) was assessed against observed, daily concentration measurements as well as hypothetical data collection frequency and timing (derived from sub-sampling the same data sets).

**252 Taxa-focused approach to standardizing use of population models in ecological risk assessment**

*J. Awkerman, S. Raimondo, USEPA / Gulf Ecology Division; A. Schmolke, Waterborne Environmental, Inc. / College of Biological Sciences; K.E. Kapo, Waterborne Environmental, Inc.; N. Galic, Syngenta Crop Protection, LLC / Environmental Safety; V. Forbes, University of Minnesota / Ecology, Evolution & Behavior*

In spite of widespread acceptance of the utility of population modeling and advocacy of these approaches for more ecologically relevant perspective, they are not routinely incorporated in ecological risk assessments (ERA). A systematic framework for situation-specific model development is one of the major challenges to broadly adopting population models in ERA. As risk assessors confront the multitude of species and chemicals requiring evaluation, adaptable model templates and taxa-specific guidance on model parameterization would facilitate this process. We build on previous work that created a framework and decision guide for developing population models for ERA by focusing on anuran amphibians. Anurans have a unique life cycle with varying habitat requirements and physiological processes. These species belong to the amphibian class, which is facing global population declines, due in large part to anthropogenic stressors, including pesticide effects. A stage-based matrix model broadly represents the anuran life cycle. We synthesize information from databases and literature relevant to amphibian risks. At the individual, population, and ecological levels we identify traits that influence inherent sensitivity, population vulnerability, and environmental constraints. We also outline methods of modifying a basic population model to suit specific risk assessment needs with appropriate scale and parameterization to evaluate pesticide effects. A standardized population model approach for anuran ERA offers an example method of identifying potential risks and determining long-term impacts of chemical stressors to populations across taxonomic groups.

**253 Mechanistic modeling of chemical stressors: Comparison of toxic effects on different trout species**

*C. Accolla, V. Forbes, University of Minnesota / Ecology, Evolution and Behavior*

Ecological risk assessment ought to make predictions about the likely effects of chemical contaminants on populations and ecosystems. However, current approaches often fall short because methods for estimating and integrating exposure and effects are based on overly simplistic assumptions. Mechanistic models have an essential role to ensure better predictive capacity, integrating the effects of chemicals across multiple levels of ecological organization. Furthermore, models can extrapolate both stressor impacts and life histories across species that cannot be tested in the lab. The aim of this research is to compare the impacts of a generalized stressor affecting ingestion among three trout species: the rainbow trout (*Oncorhynchus mykiss*), the brown trout (*Salmo trutta*)and the threatened greenback cutthroat trout(*Oncorhynchus clarkia stomias*). The comparison is performed at individual and population scales. To this end, we developed an individual-based model (IBM) for each trout species.

The individual description is based on Dynamic Energy Budget (DEB) theory, which describes the metabolic organization of organisms and which is a standardized theory, tested for many species in different contexts. Each species is characterized by a set of DEB parameters, as well as by different seasonal reproduction periods. At the individual level, we compare scenarios in which temperature is consistently optimal or fluctuating, while food is always unlimited. Responses to the toxicant show that the relative impact of the stressor, calculated as a percentage decrease in growth or fecundity compared to control, is the same among species and among scenarios. However, temperature fluctuations delay reproduction and reduce length and fecundity. At the population scale, we represent a more realistic environment, in which temperature and food fluctuate seasonally. Results at the individual level suggest that differences among DEB parameters do not influence model outputs. A good representation of temperature fluctuations, instead, seems to be crucial. This result is particularly relevant if corroborated at the population scale, meaning that well sampled and well parametrized species can be used as surrogates for closely related species for which data are not available.

**254 Modeling effects of stressors at population scale from observed effects at individual scale**

*M. Vaugeois, University of Minnesota-Twin Cities / Department of Fisheries, Wildlife, and Conservation Biology; P. Venturelli, Ball State University / Department of Biology; V. Forbes, University of Minnesota / Ecology, Evolution & Behavior*

Environmental stressors, such as invasive species, climate change and chemical pollution increasingly threaten ecosystems and their services. These stressors can have multiple lethal or non-lethal effects on individuals, such as increasing mortality rates, decreasing reproduction and growth rates or changes in other life-history traits. These effects are often measured at the individual scale for experimental convenience. These experiments provide essential information about stressor hazardousness and about the biological mechanisms of toxicity in exposed organisms. However, ecological management and protection generally occur at population, community or ecosystem levels. Moreover, observed effects at the individual scale cannot be taken as proxies for effects at higher scales of biological organization. Thus, there is a need to extrapolate the consequences of stressors at the population scale from those observed at the individual scale. Mechanistic modeling is an excellent tool for this purpose. In this work, we aim to compare how individual-scale effects translate to the population scale in different ecosystem types. For this purpose, we developed an individual-based model (IBM) of a well-known surrogate fish species, the fathead minnow (*Pimephales promelas*). In this model, individual fishes, whose metabolism is described with the Dynamic Energy Budget (DEB) theory, are simulated in ecosystems controlled by either food availability or predation. In addition, we simulated individual fishes that are also exposed to a toxicant. We considered scenarios in which the toxicant effects were lethal (i.e., increased vulnerability to predation for particular life stages) or non-lethal (i.e., effects on ingestion, maintenance, reproduction or growth). Results show that the intensity of effects at the population scale on fish density varies depending on which individual-level toxicant effects are considered. More importantly, results highlight that the effects on fish density strongly depend on ecosystem type such that individual effects were potentially overcompensated, compensated, partially compensated or not compensated at all. These results are particularly relevant in the context of ecological risk assessment because they underline the importance of the interplay between stressors and the density-dependent mechanisms regulating population dynamics.

**255 Setting a species-specific population model in the context of an aquatic food web model: A case example for the Topeka shiner**

*A. Schmolke, Waterborne Environmental, Inc. / College of Biological Sciences; S. Bartell, Cardno; C. Roy, N. Green, D. Perkins, Waterborne Environmental, Inc.; N. Galic, Syngenta Crop Protection / Environmental Safety; R. Brain, Syngenta Crop Protection, Inc. / Environmental Safety*

For species listed as threatened or endangered under the Endangered Species Act (ESA), higher-tier environmental risk assessments (ERAs) include assessing potential overlap of pesticide use patterns and the species' geographical range. However, potential risks to populations also depend on temporal aspects of exposure and effects as well as interactions with ecosystem-mediated effects. We developed an individual-based population model (IBM) for the Topeka shiner (*Notropis topeka*), a fish species listed as endangered, and linked it with an aquatic food web model (comprehensive aquatic systems model, CASM). The CASM was parameterized and calibrated to represent the waterbody conditions and aquatic species community in a small headwater pool in Iowa, representative of a Topeka shiner's key habitat within its geographical range. In the IBM, Topeka shiners feed on several groups in the aquatic food web according to published diet studies. Fish are simulated to grow according to a bioenergetics submodel that considers consumption, respiration and waste losses. We modelled the effects of alterations of the food web on the Topeka shiner populations by systematically reducing the available biomass of groups that the shiners consume. These alterations are generic simulations of the potential effects of pesticide exposures in agricultural landscapes around the shiner's habitat. Potential pesticide effects on the food web depend on the compound, magnitude, timing and duration of exposure, and are simulated in the model by applying daily concentrations of a pesticide in the simulated waterbody which can be derived from field measurements or fate models. The linked models provide a platform for the assessment of potential direct and food-web mediated indirect effects of stressors such as pesticides on species populations.

## Human Health and Ecological Risk Assessment of Per- and Polyfluoroalkyl Substances

**256 Application of revised methodologies for default guideline value derivations: PFOS in freshwater**

*G.E. Batley, CSIRO Land and Water / Centre for Environmental Contaminants Research; R.A. van Dam, ERISS / Department of the Environment and Energy; K.E. Broadgate, Golder Associates Pty, Ltd.; M.S. Warne, The University of Queensland / School of Earth and Environmental Sciences; N.L. Cooper, Golder Associates Ltd / Department of Zoology; C. Brumley, AECOM Australia Pty Ltd*

As part of a review of the Australian and New Zealand guidelines for fresh and marine waters, new default guideline values (DGV)s have been derived for a range of priority chemicals. A reassessment of the scientific underpinnings of DGV derivation was also undertaken paying particular attention to the acute and chronic definitions for tested species, and guidance on the use of species sensitivity distributions (SSDs) including the assessment of modality, determining the reliability of the derived DGVs, preferred toxicity endpoints and the use of multigenerational tests (Batley et al., 2018; Warne et al., 2018). PFOS was one of the chemicals having a new DGV, derived by Golder. This presentation focuses on subsequent changes to the derivation methodology for such bioaccumulating toxicants with assessment of modality where mode of action is uncertain or unknown. The preferred DGV derivation method is to use SSDs. For compounds such as PFOS which bioaccumulate and biomagnify, the 99% species protection value (PC99), rather than the PC95, is recommended for slightly to moderately disturbed ecosystems. The Canadian DGV of 6.8 µg/L is a PC95 value from an SSD. The EU concluded that there were insufficient chronic data to derive an annual average environmental quality standard (EQS) using an SSD, so applied an assessment factor of 10 to the lowest NOEC to obtain a value of 0.23 µg/L. However, to be protective of human health, an EQS of 0.00065 µg/L was chosen for inland surface waters. In the Netherlands, RIVM applied an assessment factor of 100 to obtain a maximum permissible concentration of 0.023 µg/L, but for secondary poisoning derived a value of 0.0026 µg/L. In Australia, eighteen chronic data from five taxonomic groups, including a sensitive multigenerational 180-d growth test on zebrafish, were used in an SSD plot that spanned an unusual seven orders of magnitude. The very low slope of the tail of the SSD resulted in the 99% protection value being extrapolated to 0.00023 µg/L. There was a separation of sensitive animal data and less sensitive plant data, implying bimodality. The animal data spanned five orders of magnitude with a PC99 value of 0.039 µg/L. Applying a newly developed weight of evidence screening for modality assessment (Warne et al., 2018), it was concluded that the data were bimodal and that the proposed DGV should be based solely on animal data. This, and other significant considerations for the PFOS DGV derivation will be discussed.

**257 Bioaccumulation of Per- and Polyfluoroalkyl Substances (PFASs) from Exposure to Aqueous Firefighting Foam (AFFF) Mixtures in Mouse and Human Serum**

*C.A. McDonough, Colorado School of Mines / Civil and Environmental Eng; S. Choyke, Duke University / Environment; J.C. DeWitt, East Carolina University / Pharmacology and Toxicology; J. Adgate, University of Colorado Denver / School of Public Health; C.P. Higgins, Colorado School of Mines / Department of Civil and Environmental Engineering*

Per- and polyfluoroalkyl substances (PFASs) are a class of highly fluorinated synthetic organic compounds that have become ubiquitous global pollutants due to their remarkable environmental persistence. Recently, PFASs have entered the national spotlight due to widespread contamination of U.S. drinking water supplies, raising serious concerns about their bioaccumulation potential and health effects. Aqueous firefighting foams (AFFFs) used to combat hydrocarbon fuel-based fires are a significant source of PFASs in potable water. More information on bioaccumulation, biotransformation, and biological effects of AFFF-associated PFASs is rapidly needed to understand health risks posed by widespread, long-term AFFF contamination of drinking water. Here, samples of serum from mice dosed with a commercial AFFF formulation, which is a mixture of hundreds of PFASs, were analyzed via liquid chromatography with quadrupole time-of-flight-mass spectrometry (LC-QToF-MS) to screen for PFASs and their transformation products. Serum samples from 200 humans in the Fountain-Widefield-Security communities of Colorado, where widespread AFFF contamination of drinking water has occurred, were also collected and analyzed by LC-QToF-MS. A custom high-resolution mass spectral library and extensive extracted ion chromatogram (XIC) list developed at Colorado School of Mines were used to screen samples for novel fluorinated compounds. To evaluate bioaccumulation potential, the composition of PFASs in mouse serum was compared to the commercial formulation used in dosing to determine which PFASs were relatively enriched in the body and which were depleted. Preliminary results suggest that some of the PFASs that appear to be most bioaccumulative, including unsaturated, chlorinated, and oxygen-containing derivatives of C7-C11 perfluoroalkyl sulfonates, are novel PFASs for which little to no biomonitoring or toxicological data is currently available.

**258 Dietary Exposure of Japanese Quail (*Coturnix japonica*) to Perfluorooctane Sulfonate: Effects on Reproduction and Chick Survivability and Growth**

*S.J. Bursian, J.E. Link, Michigan State University / Animal Science; M. McCarty, M.F. Simcik, University of Minnesota / Division of Environmental Health Sciences*

Aqueous film forming foam (AFFF) has been used by the Department of Defense for over 40 years for fire-training and emergency response activities. As a result of these activities, ground water, surface water and biota in the vicinity of relevant military installations have become contaminated with perfluorooctane sulfonate (PFOS), perfluorooctanoic acid (PFOA) and other poly- and perfluoroalkyl substances (PFASs). As part of an effort to develop avian ecotoxicity information for compounds associated with AFFF, the effects of dietary PFOS on reproduction and chick survivability and growth in an avian species recognized as a surrogate for wild avian species, the Japanese quail (*Coturnix japonica*), were determined. Day-old Japanese quail were administered PFOS at analyzed dietary concentrations of 0, 2.1, 4.0, 8.6, 14 or 18 µg/g feed for a total of 140 days. At four weeks of age, 16 male/female pairs were assigned to each treatment group. At 10 weeks of age, females began laying eggs. For the next 10 weeks, eggs were collected daily, set weekly and incubated for 18 days. On the day of hatch, hatchlings were counted, weighed and placed in a brooder battery on clean feed for two weeks. Unhatched eggs were opened to determine the stage of development. At the end of the second week, 10 chicks from each treatment were euthanized and sampled for blood and liver. Liver and pooled serum samples were analyzed for PFOS. At the end of the 10th week of egg laying, adult birds were euthanized and sampled for blood and liver for PFOS analysis and liver, kidneys, lung and thyroid glands for pathology. At the end of the trial, body weights of adult quail fed feed containing PFOS were significantly less compared to control body weights. Egg production of hens fed PFOS was significantly less in all treatment groups except the 14 µg/g feed group compared to controls. Hatchability of eggs was significantly less in the 8.6, 14 and 18 µg PFOS/g feed groups compared to hatchability in the control group. Survivability of chicks in the PFOS treatment groups through the first week of age was generally less compared to the control group whereas body weights of two-week-old quail were not significantly different across treatments. Results of this study suggest that dietary exposure of Japanese quail to PFOS has an adverse effect on reproduction and chick survivability at concentrations ranging from 2.1 to 18 µg/g feed, but chick growth is unaffected.

**259 Observed distribution of PFOS in biota in a tropical environment**

*S. Richards, Coffey; M.S. Bowersox, Tetra Tech, Inc. / Laboratory Department; A. Wightwick, Coffey Pty Ltd / Environments; I. Dixon, Eco Logical Australia; R. Rees-Scott, Australian Department of Defence / PFAS Investigation and Management Branch / Infrastructure Division*

Australian Department of Defence is undertaking a nationwide investigation program to assess the nature, extent and impact of PFAS contamination from legacy AFFF use on Defence sites. Where the abiotic data indicated a plausible pathway or elevated risk to human health or ecology, sampling and testing of biota was also conducted. This paper presents key observations from biota testing conducted across aquatic, riparian and terrestrial settings related to two RAAF Bases in the Northern Territory of Australia. The sites are in tropical climates and biota included a broad range of native and introduced species. Combined across the two sites, over 50 vegetation, 120 terrestrial vertebrates (including mammals, reptiles, amphibians and birds), 50 invertebrates and 700 fish samples were tested. Analysis indicated differing patterns of accumulation in animals, with low concentrations in green ants (less than 4 mg/kg) and high levels in reptiles (up to 5,400 mg/kg) in the same area. Sampling across wet and dry seasons also showed accumulation and elimination at different rates in fish species, with large long-lived species showing little seasonal trend, but an increase with age, and smaller species showing a distinct seasonal fluctuation independent of age. The results of the testing have been used in ecological risk assessments to validate food web relationships, identify the most significant pathways and provide a baseline for future reference.

**260 An evaluation of the potential impact of perfluorooctane sulfonate (PFOS) to mink and otters: Current perspectives**

*J.L. Newsted, Natural Resource Technology, an OBG Company*

Perfluoroalkyl acids (PFAAs) are synthetic fluorinated organic compounds that can be released to the environment during manufacturing processes, from commercial products and applications, or indirectly via oxidation of precursor molecules containing perfluoroalkyl chains. While PFAAs have received increased attention in monitoring programs, the assessment of the potential risks PFAAs pose to wildlife is still being investigated. Few ecologically relevant toxicity studies have been conducted with wildlife exposed to PFAAs and this is particularly true for mammalian species. To address this issue, we used the USEPA Great Lakes Initiative (GLI) to derive protective values for perfluorooctane sulfonate (PFOS) in mink, a sentinel wildlife species. Benchmark dietary and liver PFOS concentrations were determined using data from a multigenerational rat study and a mink pharmacokinetic study. Bioaccumulation and biomagnification factors were used to extrapolate toxic doses water value (WV) for mink and otters. While the GLI approach focuses on food web extrapolations to water, the literature indicates that sediments may also be an important vector of PFOS to aquatic organisms and upper trophic level predators. As a result, the GLI may produce overly protective water values. A simple food web model was used to estimate the significance of water and sediments as sources of PFOS to mink. The results from this analysis indicated that the sediments are a source of PFOS to mink and should be taken into consideration when setting water values. Finally, these wildlife values and tissue benchmarks are discussed relative to current and historical PFOS concentrations measured surface water and mink.

**261 Firefighters' accidental exposures to Aqueous Film Forming Foams- A case study**

*S. Crispo Smith, California Environmental Protection Agency / Department of Toxic Substances Control; J. VillaRomero, California Department of Toxic Substances Control; M. Wang, ECL California Dept. of Toxic Substances Control / Enviromental Chemistry Laboratory; J. Park, M. Petreas, California Environmental Protection Agency / Department of Toxic Substance Control / Environmental Chemistry Laboratory*

Per and polyfluoroalkyl substances (PFASs) are a class of compounds extensively used in food packaging, commercial goods, and aqueous film forming foams (AFFF) used to extinguish fires. Some of these compounds, such as perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), are highly persistent in the environment and biota, and can cause adverse health effects, such as endocrine disruption, immunological suppression, and cancer. Concerns about AFFFs contaminating ground water have led to restrictions on their use. Additionally, concerns regarding occupational exposures of firefighters to PFAS contained in AFFFs are mounting. We report a case study involving 3 professional firefighters who were accidentally splashed with AFFF in 2015. Serum samples submitted by their physician were analysed for PFAS using targeted and non-targeted analytical approaches using online-SPE-HPLC-MS/MS system, offline SPE and UHPLC-MS/MS, and UHPLC-QTOF-MS. Our targeted analysis showed that these firefighters had PFOS, PFOA and PFHxS above the $90^{th}$ percentile of NHANES (males, 2013-14). Additionally, several markers of historical and current use AFFF including PFOS, 6:2 FtS and short-chain carboxylates (e.g. PFHxA) were elevated in those firefighters compared to other study populations. Using our in-house PFAS database with ~400 PFAS compounds, suspect screening analysis (SSA) also confirmed those compounds with high intensities. However, we did not detect any novel AFFF formulations and transformation products that we identified in wastewater samples previously. Unknown identification using chemical formula generator, polyfluorine mass defect filter, and fragmentation studies are underway. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

**262 Development of Risk Based Screening Criteria for Poly and Perfluoroalkyl Substances: Recommendations, Challenges, and Research Gaps**

*J. Brown, Colorado School of Mines / Civil and Environmental Engineering; J.M. Conder, J. Arblaster, Geosyntec Consultants; C.P. Higgins, Colorado School of Mines / Department of Civil and Environmental Engineering*

Poly and perfluoroalkyl substances (PFASs) have been identified as chemicals of concern in agricultural soils, biosolids-amended soil, and irrigation water due to their toxicity, persistence, and bioaccumulation potential. The agricultural use of PFAS-contaminated irrigation water, municipal and industrial biosolids, and municipal compost can all contribute to the exposure of PFASs to food crops. Soil irrigated with contaminated water may become contaminated over time resulting in additional exposure pathways to food crops. The unintended uptake and accumulation of PFASs in edible crop plants is an important and continuing concern for protecting human health. In particular, there is an urgent need for regulatory agencies to accurately understand accumulation in the edible portion of food crops as these foods are often consumed fresh or with minimal processing. Recognition of PFASs in food as an important contributor to human exposure, as well as the identification of PFAS-impacted groundwater and soils in areas with agricultural activities, has resulted in several studies on the uptake of PFASs into crops. Using available crop-specific bioaccumulation factors (BAFs) and consumption rates for food crops typically grown in urban gardens and farms, as well as best available or derived human health reference doses, risk based concentrations (RBCs) for PFASs in contaminated soil and irrigation water were determined for adults and children. The RBCs for six perfluoroalkyl carboxylic acids and three perfluoroalkyl sulfonic acids in soil and water are compared to other risk-based pathways and available health advisories or criteria. Preliminary results indicate the RBCs for perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA) in soil are lower than available EPA or state residential soil screening levels; whereas, the RBCs for PFOS and PFOA in water are generally less conservative than the current health advisory for drinking water of 70 ng/L. Typically, non-root vegetables (e.g., lettuce) as compared to root vegetables, fruit, wheat, and corn have the lowest RBCs for contaminated soil and water; however, the RBCs are highly site specific due to varying soil organic carbon content, growing season, and consumption. The variability of the RBCs and model parameter sensitivity (e.g., BAFs) are evaluated. The BAFs vary considerably between crop types, experimental conditions, and compounds. Key research needs are discussed and data gaps are identified.

**263 Monitoring and Analysis of Poly and Perfluorinated Alkyl Substances in the European Honey Bee at Williamtown, New South Wales, Australia**

*C.A. Sonter, University of New England, Armidale NSW / Environmental and Rural Sciences; D. Evans, Beca Pty Ltd; G. Stevenson, National Measurement Institute; S. Wilson, C. Laidlaw, University of New England / School of Environmental and Rural Science*

Poly and perfluorinated alkyl substances (PFAS) contaminate the environment around the Williamtown Royal Australian Air Force site, NSW, Australia. The PFAS compounds are sourced from the Aqueous Film Forming Foam, historically used for defence force firefighting activities. Water soluble and persistent, PFAS have been detected in the ground and surface water, sediment, soil, and aquatic and terrestrial biota both on and off the site. Concerns regarding exposure and risk are significant with sensitive down-gradient receptors and local hydrogeological aspects that conflate exposure. Bees were selected as the test subject due to their foraging nature and range, link to human receptors from honey consumption and key pollination role. To our knowledge, analysis and investigation of PFAS accumulation in bees and honey has not been investigated in Australia to date. For one year, we monitored bee (*Apis mellifera*) tissue and honey from four hives situated within foraging range (2.5-8 km) of the perimeter of the site that includes the NSW EPA Special Investigation area, and one non-contaminated control hive. Composited bee tissue (n =

20) and honey (n = 20) was tested for PFAS compounds using an isotope dilution method combined with Liquid Chromatography Tandem Mass Spectrometry adapted for bee and honey matrix analysis. Our results indicated that PFAS concentrations, in particular perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA), in bee tissue and honey were equal to test results from our control site (< 0.003 mg $kg^{-1}$). Quality control work indicated acceptable spike recovery, accuracy and precision. The PFAS control spike sample recoveries ranged from 70-138% (average 103%), honey matrix PFAS spike recoveries ranged from 77-125% (average 100%). Isotopically labelled internal standard recoveries ranged from 60-80% for PFOA and PFOS. The screening tolerable daily intake value for food consumption in Australia is less than 0.02 and 0.16 µg/kg/week for PFOS / PFHxS and PFOA, respectively (FSANZ, 2016). This preliminary study showed no evidence of PFAS uptake in bees collected within a foraging range of a significantly contaminated location. The monitoring indicated that human exposure from consumption of honey from the hives sampled was not a concern. Potential uptake pathways, bee foraging behaviour and PFAS availability were evaluated to interpret these findings.

## Persistence and Biodegradability Assessment

**264 Biodegradation screening methods: Limitations and areas for improvement**

*K. McDonough, J. Menzies, N.R. Itrich, K. Casteel, P&G / Environmental Stewardship Sustainability*

For down the drain disposed chemicals, the OECD 301 Ready Biodegradation series of tests are widely used by scientists and regulators to assess aerobic biodegradability typically using inocula from activated sludge wastewater treatment plants. These tests can be useful screening tools as they are well prescribed, use indirect measures of biodegradation by following carbon or oxygen, and are relatively inexpensive and easy to perform. However, the usefulness of these studies is limited due to the conservative nature of the tests. These tests employ high test chemical concentrations and low levels of inocula that are not realistic when compared to actual environmental conditions. The unrealistically high test chemical concentrations can lead to issues with solubility and microbial inhibition under the test conditions. The low levels of inocula limit the microbial diversity which is unrealistic compared to actual environmental compartments and also leads to extended time periods needed for the microbes present in the study to adapt to the test chemical as the only food source and for the microbial population to increase to a sufficient level to degrade the high concentration of test chemical. These conservative test conditions are further confounded by the stringent pass criteria and short test duration (28 d). This presentation will use case studies of different chemicals to highlight limitations of the OECD 301 test method and propose potential areas for improvement. The first case study will explore issues related to chemical solubility and microbial inhibition and the impact of modifying the test design to overcome these issues. The second case study will explore the impact of chemical bioavailability and mass transfer limitations and discuss the importance of test extension to overcome these issues. The final case study will evaluate microbial adaptation both in the field and in a lab setting and highlight the importance of evaluating environmentally relevant adaptation in an assessment of biodegradability.

**265 Fate and Remediation of an Extremely Recalcitrant Emerging Contaminant: 1,2,3-Trichloropropane (TCP)**

*P.G. Tratnyek, Oregon Health & Science University / School of Public Health; A. Salter-Blanc, Jacobs; T. Torralba-Sánchez, Y. Lan, G. O'Brien Johnson, R. Johnson, Oregon Health & Science University / School of Public Health; E. Bylaska, Pacific Northwest National Laboratory / Environmental Molecular Sciences Institute*

1,2,3-Trichloropropane (TCP) is an emerging contaminant of exceptional concern because it is extremely toxic (the California State Water Resources Control Board recently adopted an MCL of 5 ppt), wide-spread due to a variety of industrial and agricultural uses, mobile in contaminated groundwater, and extremely persistent. The overall persistence of TCP was apparent from early lab and field studies that found essentially no evidence for degradation by biological or chemical pathways. More recent and intensive studies have identified systems that degrade TCP by hydrolysis, oxidation, and/or reduction, but all of these systems involve highly optimized or extreme conditions, and the resulting degradation kinetics are still slow relative to many contaminants. The reactivity of TCP is similar to that of other lesser chlorinated aliphatic hydrocarbons (LCHCs), which have only one halogen substituent per carbon (e.g., 1,2-dichloroethane). That makes these compounds very poor targets for dichlorination by hydrogenolysis (which often is the preferred route of microbial dehalogenation). However, once TCP undergoes reductive elimination (often the preferred abiotic pathway), the resulting intermediate (allyl chloride) is readily reduced to fully dechlorinated products. Thus, while TCP degradation is hard to initiate by reduction, problematic intermediates do not accumulate. We have shown this with a variety of abiotic reductants (esp. zerovalent zinc), modeled the kinetics, and explained the results using molecular modeling. The implications generally are not promising for biodegradation of TCP, but they are consistent with the various, recent reports of TCP degradation by a few microbial systems. Because data on the degradation of TCP are so sparse, models that predict (bio)degradation are not well calibrated for this or other LCHCs, so predictions of their persistence are not very reliable.

**266 Kinetics of Human Pharmaceutical Conjugates and the Impact of Transformation, Deconjugation, and Sorption on Persistence in Wastewater Bioreactors**

*A. Brown, University of Manitoba / Chemistry; J. Ackerman, University of Manitoba / Department of Biosystems Engineering; N. Cicek, University of Manitoba; C.S. Wong, University of Winnipeg / Department of Chemistry*

The purpose of this study was to address the knowledge gap of simultaneous in vitro transformation of pharmaceuticals and their metabolite conjugates using real wastewater, and to corroborate the results seen in our previous field study. Wastewater parameters such as components of primary or secondary wastewater, addition of air, and/or waste activated sludge (WAS) could influence the kinetics of removal or transformation. Under a realistic wastewater treatment plant HRT (< 2h), both acetaminophen and its sulfate were rapidly degraded (>99%). There was evidence for in vitro sulfation of propranolol, with concurrent removal of propranolol; and also deconjugation of N-acetylsulfamethoxazole and sulfamethoxazole glucuronide contributing to the increase of the parent sulfamethoxazole. Thyroxine was resistant to degradation across all treatments while thyroxine glucuronide was shown to be rapidly deconjugated (>90% in < 2h). Suspended solids analysis at the 0h and 24h timepoints revealed that in absence of WAS, sorption is another major mechanism of removal for acetaminophen, propranolol, sulfamethoxazole, and thyroxine. However, in the presence of WAS, suspended solids concentrations decreased for all analytes by the 24h timepoint. These results indicate that both conjugation and back-transformation are compound specific and dependent on parameters such as HRT, addition of WAS, and suspended solids levels.

**267 Influence of structure and nanoporosity of sediment organic matter on mineralization of benzo(a)pyrene by hydrogen peroxide**

*Y. Ran, Guangzhou Institute of Geochemistry / Chinese Academy of Sciences; C. Zhuo, Guangzhou institute of Geochemistry / Chinese Academy of Sciences / State Key Lab of Organic Geochem; D. Zhang, Y. Yang, Guangzhou Institute of Geochemistry / State Key Laboratory of Organic Geochemistry*

Benzo[a]pyrene (BaP) in sediments is persistent, bioaccumulation, genetically toxic, and carcinogenic to organisms. We here investigated how the mineralization of 7-$^{14}$C-benzo[a]pyrene by $H_2O_2$ treatment in aged sediments from the Pearl River Estuary to South China Sea is influenced by the structure, fractions, and nanoporosity of sedimentary organic carbon (OC) by using mineralization bottles and liquid scintillation instrument. Unstable OC (USOC), stable OC (SOC), mineral-protected OC (MOC), and chemically resistant OC (ROC) was fractionated in the sediments. The structure and nanoporosity of the ROC fractions were characterized by NMR and CO2 adsorption techniques, respectively. It was found that BaP mineralization ratios and USOC percentages gradually decreased, but ROC percentages and aliphatic contents gradually increased from the estuary samples to the offshore marine samples. A first-order, two compartment kinetics model described the mineralization process very well ($R^2$ =0.990). The mineralization ratios of BaP at 408 h in the sediments showed a significant positive correlation with the USOC contents ($R^2$=0.847, $p$< 0.05), and a negative correlation with the ROC contents ($R^2$=0.780, $p$=0.06), suggesting that the ROC fractions can protect BaP from the oxidation. Significant and negative correlations among the mineralization ratios of BaP, kinetics parameters, and the aliphatic-C, alkyl-C, and (CH2)n-C structures, and nanopore volumes (Vo) suggested that the aliphatic moieties and nanooposity play a crucial role in protecting BaP from being mineralized by the hydroxyl radicals. This study indicated that the important role of the USOC, ROC, and aliphatic moieties and the nanoporosity of ROC in the mineralization of BaP in sediments during $H_2O_2$ treatment. Keywords: 7-$^{14}$C-benzo[a]pyrene; mineralization; hydrogen peroxide, recalcitrant OC; aliphatic carbon, nanooporosity

**268 Recalcitrant Petroleum Spills: Biodegradation and Metabolites**

*U. Hellmann-Blumberg, California EPA / Dept. of Toxic Substances Control; R. Steenson, California EPA / SF Bay Water Board*

Although petroleum spills are often considered highly susceptible to processes that facilitate natural attenuation it is not unusual to come across a mature release site with levels of petroleum hydrocarbons that cause regulatory concern. Recent interest in high “TPH” levels in groundwater associated with some petroleum sites has fueled a debate about petroleum hydrocarbon metabolites (partial breakdown products with much higher water solubility than parent hydrocarbons). The debate initially focused on the potential toxicity of weathered versus fresh petroleum hydrocarbon mixtures but it since has become clear that a satisfactory resolution of this issue will also require a better understanding of what happens with petroleum hydrocarbons after their release into the environment. Thus, a literature review on hydrocarbon biodegradation that complements and supports the Petroleum Metabolites Literature Review and Assessment Framework published in 2016 by the San Francisco Bay Regional Water Quality Control Board was conducted and part of that is being incorporated into the forthcoming ITRC guidance on TPH Risk. The fact that at many sites petroleum hydrocarbon mixtures appear to degrade with astonishing ease compared to typical releases of halogenated chemicals, for instance, has given rise to “reverse-engineered” theories about biodegradation. Such theories match observations at simple sites but tend to misapply bits of chemistry and thus fail to provide insight into complex or recalcitrant sites. The latter tend to have large anaerobic portions with a vastly greater microbial and chemical complexity than fully aerobic sites. Successful evaluation and management of slowly degrading petroleum sites requires the understanding of anaerobic biodegradation including basic chemistry, biochemistry and microbiology concepts as well as the ever-expanding options for the investigation of petroleum biodegradation.

**269 Marine biodegradation screening testing version 2.0**

*A. Ott, T. Martin, Newcastle University / School of Engineering; G. Whale, Shell Health / Risk Science Team; B. Rowles, Cefas Lowestoft Laboratory; N. Robinson, I. Still, EOSCA; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; A. Baumbusch, Norwegian Environment Agency; B. Hubesch, CEFIC – European Chemical Industry Council; R. Davenport, Newcastle University / School of Engineering*

Exponential growth of the human population has been accompanied by increased manufacture and use of chemical compounds. To classify the fate and behaviour of these compound in the environment, a series of international standardised biodegradation screening tests (BSTs) were developed over 25 years ago. In recent years, regulatory emphasis (e.g. REACH) has shifted from measuring biodegradation towards prioritisations based on chemical persistence. In their current guise, BSTs are ineffective as screens for persistence. They are prone to high levels of variation and produce a large number of fails, many of which can be considered false negatives, wherby a chemical fails a test not because of its recalcitrance, but rather because the test itself has failed. Based on previous regulatory recommendations and research conducted, two key methodological modifications to potentially improve the marine BST (OECD 306) were high lighted: (i) increasing bacterial cell concentrations to better represent the bacterial diversity inherent in the sampled environments; and (ii) increasing test durations to investigate extended lag phases observed in marine assessments. During 2016-2018 an improved marine BST protocol incorporating both increased cell concentrations and test duration was assessed using a set of reference chemicals in a multi-institutional ring test across 13 laboratories in the UK, Norway, Germany, Italy, Canada, USA and Japan. In comparison to the standard marine BST, the improved marine BST was more reliable and less variable at characterising the environmental persistence of the reference compounds. Extending the test durations beyond 28 days allowed for a more reliable characterisation of environmental persistence. There was a positive relationship between total cell counts and biodegradation potential. However, the greatest rates and extents of degradation were not necessarily observed at the laboratories with the highest cell concentrations, suggesting that cell concentration is not the only factor influencing the degradation potential of an environmental sample. Preliminary microbial analysis suggests that the composition of the sampled environment may have a greater influence on biodegradation test outcome than diversity.

**270 Influence of microbial adaptation in persistency testing**

*B.A. Poursat, University of Amsterdam / Institut for Biodiversity and Ecosystem Dynamics; J. Parsons, University of Amsterdam / IBED-ELD; P. de Voogt, R. Helmus, University of Amsterdam / IBED; R.J. van Spanning, M. Braster, VU University Amsterdam*

Regulatory determination of the persistency of organic chemicals is often based on the results of OECD ready biodegradability tests (RBTs). These tests, however, suffer from several problems that lead to a high variability of the results and, hence, to difficulties in their interpretation. The origin and history of the inocula is one of the major causes of that variability. Nowadays, it is evident that results of RBTs change over time as microbial populations apparently adapt to metabolise previously persistent chemicals. Several studies also show an improvement of the biodegradation rates even after a short period of pre-exposure to the tested chemical. As such, there is a need to assess the influence of this process on biodegradability tests. In this study we assessed the extent of the inocula origin influence on the outcome of biodegradability testing. For this, we compared the biodegradation capacity of five different wastewater treatment plants across the Netherlands to eliminate carbamazepine, n-methylpiperazine, metformin, diclofenac and 4-chloroaniline. Most of these products can be considered as emerging pollutants and are environmentally persistent. In a second time, we used chemostat systems to expose activated sludge microbial communities to carbamazepine, n-methylpiperazine, metformin and 4-chloroaniline for several months under defined conditions. In both experiment, the biodegradation capacities of the inocula were assessed in biodegradation testing, following the OECD 310 guideline, and changes in community structure were followed by Illumina amplicon sequencing in time. Removal of tested chemicals and their transformation products were determined by GC-FID and LC-MS/MS. Results of these experiments show difference of biodegradation capacity between the tested inocula. Long term exposure of a microbial community to n-methylpiperazine in chemostat leads to an enhanced biodegradation of this compound. These results will allow a better understanding of the relationship between microbial adaptation and biodegradation performance. Moreover, microbial communities exposed to metformin were able to degrade its known persistent transformation product, guanylurea, which is persistent in fresh water. Ultimately they will also allow more realistic predictions of their biodegradation in the environment compared to those obtained using standard testing protocols.

**271 Towards an improved understanding of persistence in the 21st century**

*G. Whale, Shell Health / Risk Science Team; K. van Ginkel, AkzoNobel; R. Davenport, Newcastle University / School of Engineering; J. Parsons, University of Amsterdam / IBED-ELD; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment*

There is increasing concern that progress in the scientific understanding of factors which influence the outcome of chemical persistence (P) assessments (particularly biodegradation) are not fully recognised in existing regulations and environmental risk assessments. As all biodegradation tests have their limitations, which are accentuated for 'difficult to test' substances, failure to recognise these can potentially lead to many chemicals being incorrectly labelled as 'P' persistent. Many of the shortcomings of existing biodegradation studies have been recognised and discussed in a series of ECETOC reports and workshops. Key recommendations from these have been used to help develop and formulate a series of CEFIC LRI persistence assessment-related research projects, the emphasis being to address the key issues and propose methods to mitigate the existing limitations. However, many of the recent developments recommended in the multi stakeholder workshops and related research projects have not been incorporated into existing regulatory frameworks for environmental hazard and risk assessment. If the current situation is not challenged there are concerns that this will lead to an overestimation and over-classification of the hazards and risks posed by a wide range of chemicals, potentially leading to a significant amount of unnecessary testing and restrictions on advantageous chemical use. Any proposal to modify guidance needs to be based on sound science that re-examines the fundamentals of biodegradation and what existing test methods provide. Therefore, to initiate this process an overview of some of the key elements and messages coming from recent research initiatives, how these interrelate and redress some of the previously identified P assessment needs will be presented and discussed at a 'persistence' workshop to be held in Helsinki on the 27$^{th}$ September 2018. The objective being to assess how recent scientific and technological developments are given appropriate consideration by regulatory agencies and the wider community in chemical persistence assessments. This presentation will provide a summary of the key messages from the workshop regarding how best to utilise these new developments and the next steps required to start a journey to take the persistence assessment of chemicals into the 21$^{st}$ Century.

## Pesticide Runoff Pollution: Challenges and Opportunities in Prediction, Prevention and Management

**272 Adequacy and uncertainty in models and scenarios developed to estimate pesticide wash-off and runoff in residential settings**

*W.M. Williams, Waterborne Environmental, Inc.; Y. Luo, California Department of Pesticide Regulation; M.F. Winchell, Stone Environmental, Inc. / Environmental Systems Modeling*

A variety of pesticide products, including insecticides, herbicides, and fungicides, are used by homeowners and licensed Pest Control Operatiors to eradicate or deter pests on lawns and ornamentals, vegetable gardens, homes, and other structures. Pesticide detections in urban streams have resulted in an increase in research over the past decade to understand the potential for pesticide washoff to occur from various pervious and impervious application sites. Regulatory agencies, chemical registrants, and other researchers have employed a variety of approaches to model pesticide runoff associated with residential uses. This presentation compares the underlying prinicipals in several models and scenarios that have been adopted or proposed for pesticide registration review and risk assessment by regulatory agencies in the U.S. and the E.U.; and evaluates their appropriateness for risk assessment for various categories of outdoor residential-use pesticide products. The models/scenarios include the Home and Garden scenario developed for the HardSPEC model by the Food and Environment Research Agency in the U.K., residential scenarios developed for PRZM5 by the U.S. Environmental Protection Agency, and adapting urban stormwater management models including the Stormwater Management Model (SWMM5) and the P8 Urban Catchment Model.

**273 Comparison of Model Simulated and Measured Pesticide Runoff Losses from Residential Landscapes**

*M.F. Winchell, Stone Environmental, Inc. / Environmental Systems Modeling; R.L. Jones, Bayer CropScience / Environmental Safety*

Mechanistic models of pesticide fate and exposure have been developed and applied for regulatory purposes for use in the US and abroad for several decades. Models such as the Pesticide Root Zone Model (PRZM), which was originally developed to simulate processes in agricultural settings, have been extended for use in residential and other urban environments (e.g. USEPA residential PRZM scenario, CAresidentialRLF.scn). More recently, urban hydrology models, such as the Stormwater Management Model (SWMM), have been adapted to simulate pesticide transport processes from heterogeneous residential landscapes that include mixtures of pervious and impervious surfaces. The runoff transport algorithms in PRZM, SWMM, and other mechanistic and empirical models are highly dependent upon the parameterization of the surface hydrologic processes. Consequently, these can have significant impacts on the amount of off-site pesticide transport and ultimately, the predicted concentrations in receiving waters. In order to generate confidence in the predictions of pesticide fate and transport models applied to residential environments, the model predictions must be compared with and validated against field measurements. This presentation will compare measured pesticide runoff mass losses from a field study conducted in controlled outdoor residential house lots in California with estimated pesticide runoff mass losses from both USEPA PRZM scenario simulations, that have been used in recent ecological risk assessment for both pyrethroids and organophosphate pesticides, as well as from an adaptation of the SWMM model. These comparisons will provide information on the uncertainty inherent in the mechanistic models currently being used in regulatory decision making for residential pesticide uses, and offer some insight regarding the potential need to revisit model parameterization assumptions and realistic scenario development to better reflect observations from available field data.

**274 Environmental Risk Assessment of Outdoor Use Insecticides in the European Union: Current Approaches, Strengths and Weaknesses**

*P. Mason, SC Johnson EurAFNE Limited / GSARA*

Within the European Union (EU), insecticides used in outdoor residential situations are regulated under the Biocidal Products Regulation (BPR) (Regulation (EU) 528/2012), and the plant protection products regulation (PPPR) (Regulation EC 1107/2009). In the case of the BPR, guidance on estimating environmental emissions for insecticides (Product Type 18) is provided in the OECD Emission Scenario Document (2008), while subsequent technical decisions are documented in Technical Agreements on Biocides (TAB). This presentation will provide an up-to-date overview of the scenarios used for estimating emissions to relevant environmental compartments for different forms of outdoor use insecticide product under the BPR. This will include a review of assumed use patterns and treatment areas. The work will also highlight key uncertainties in the emission estimation frameworks, including the challenges associated with assessing highly localised soil exposure, as well as 'scaling-up' wastewater emissions to the catchment level. An update on latest approaches for calculating Predicted Environmental Concentrations in soil, surface water and sediment, as described in the recently updated Guidance on the

Biocidal Products Regulation Volume IV Environment (ECHA, 2017) will be provided, highlighting some of the regulatory issues that are currently under discussion in the EU.

**275 California's collaborative aquatic risk mitigation for fipronil in urban waterways and the important role of urban runoff modeling**

*N. Singhasemanon, Y. Luo, R. Budd, M. Ensminger, California Department of Pesticide Regulation / Environmental Monitoring Program*

Over the past several years, the California Department of Pesticide Regulation (CDPR) has been engaged in a collaborative problem-solving effort with pesticide and water quality stakeholders to address elevated concentrations of the insecticide active ingredient fipronil in urban runoff and receiving waters. California monitoring data from 2008–2016 indicated that fipronil was being detected at a relative high frequency (~49%) in both residential wet and dry weather runoff as well as in urban area creeks. Furthermore, fipronil concentrations exceeded USEPA's chronic and acute aquatic life benchmarks for invertebrates at 48% and 15%, respectively. In 2016, CDPR made the risk management decision to pursue mitigation to address this surface water quality concern using its regulatory authority and scientific data-driven approach. CDPR collaborated with stakeholder groups including product registrants, University of California researchers, and professional pesticide applicators to: 1) better identify fipronil sources and pathways to surface water, 2) determine the amount of load reduction necessary for successful mitigation, and 3) evaluate various application practices that could lead to practical use restrictions beyond existing product labels while maintaining product efficacy. In support of these objectives, CDPR relied heavily on data from field studies and output from urban runoff modeling. For the latter, CDPR utilized USEPA's PRZM-VVWM with various modifications to achieve a more realistic and reliable simulation of California residential runoff scenarios. This integration of predictive modeling into CDPR's continuous evaluation process (as well as initial product registration evaluation) represents a more transparent, scientifically-robust, and effective approach to protect California surface water from the use of pesticides.

**276 Management options for reducing pesticide concentrations in urban runoff**

*R. Budd, Y. Luo, M. Ensminger, N. Singhasemanon, California Department of Pesticide Regulation / Environmental Monitoring Program*

The California Department of Pesticide Regulation (CDPR) is responsible for preventing significant deleterious effects of pesticides in the environment. Pesticides are widely recognized as contaminants of concern in surface waters receiving urban runoff inputs. CDPR's Environmental Monitoring Branch frequently detects fipronil and pyrethroid insecticides at concentrations that are potentially toxic to aquatic species such that mitigation is necessary. In contrast to agricultural runoff, which has more physical treatment options available for pesticide removal, mitigation strategies addressing urban runoff frequently rely on changes to application-related practices. To address ecological concerns surrounding fipronil and pyrethroids from urban runoff, CDPR developed regulations and label use restrictions for products containing pesticides of concern. CDPR worked with several collaborators including product registrants, university researchers, and professional applicators on a collaborative approach to create application restrictions that are both effective at reducing pesticide transport off urban landscapes and adoptable by the regulated community. The additional restrictions were science driven, utilizing a predictive model to estimate runoff pesticide concentrations resulting from proposed restrictions. The modelled runoff concentrations resulting from the restricted pesticide application scenarios were supported by empirical evidence obtained during experimental field trials.

**277 Biochar amended filter socks: The future of pesticide runoff mitigation?**

*M. Moore, USDA-ARS National Sedimentation Laboratory / Water Quality and Ecology; M.J. Shipitalo, USDA-ARS / National Laboratory for Agriculture and the Environment; J. Gonzalez, USDA-ARS / National Soil Erosion Research*

Pesticide losses in surface runoff from agricultural fields following storm events is a significant water quality problem. Long-term watershed research has demonstrated that most herbicide transport, along with the highest concentrations, occurs in the first few runoff events following application. Edge-of-field runoff mitigation strategies are necessary to reduce the impact of agricultural non-point source pollution on downstream aquatic receiving systems. Traditionally used for erosion control, filter socks are mesh cloth tubes that can be filled with various sorbent materials. Biochar (derived from pyrolysis of hardwoods) has been demonstrated in the laboratory to more rapidly sorb and remove herbicides from water than other fill materials such as steel slag and tire chips. Therefore, the objective of this research was to determine if filter socks filled with woodchips or a mixture of woodchips and biochar would decrease herbicide concentrations associated with storm runoff from corn fields within the South Fork of the Iowa River during the 2017 growing season. Unfavorable climatic conditions resulting in the driest June and July on record yielded only four small runoff events during the sampling season. Results demonstrated a similar decrease in atrazine, atrazine metabolites, and isoxaflutole concentrations by both treatments (woodchips; woodchips + biochar). Only cyprosulfamide concentrations were significantly reduced by woodchips ($p = 0.0454$) and woodchips and biochar ($p = 0.0028$) compared to control (pond) concentrations. While promise is shown for using biochar-amended filter socks as an edge-of-field management practice, further evaluation must be conducted on different pesticide classes and geographical locations.

**278 Constructed wetland treatment of urban pesticides in surface water**

*Z.M. Cryder, J. Gan, University of California, Riverside / Environmental Sciences*

Pesticides are often utilized in urban environments for the control of various insect pests. Urban pesticides can be applied outdoors for structural and landscape pest control as well as indoors for household pests and veterinary flea treatments. Fipronil and synthetic pyrethroids are very commonly used for such purposes. Fipronil and its degradation products (collectively: fiproles) and synthetic pyrethroids such as bifenthrin, permethrin, and cyfluthrin are transported offsite in stormwater runoff and in wastewater following outdoor and indoor applications, respectively. Stormwater is seldom treated prior to being deposited into surface water, carrying with it all the pesticide residues washed away during runoff events. Wastewater undergoes extensive treatment, but pesticide concentrations remain sufficiently high in wastewater effluent to elicit adverse effects from sensitive aquatic organisms upon deposition into surface water. Constructed wetlands offer a promising strategy for removal of fiproles and pyrethroids from surface water. The present study focused on removal of fipronil, fipronil desulfinyl, fipronil sulfide, fipronil sulfone, bifenthrin, and cyfluthrin in a traditional constructed wetland containing planted emergent macrophytes and in a unit process open water wetland which encourages photolytic breakdown of contaminants. Influent and effluent water samples were collected monthly from both wetlands to assess the removal of the compounds of interest as a result of the physical, chemical, and biological processes occurring in the treatment systems. Plant, sediment, and water samples from the wetlands were also collected to determine the distribution of fiproles and pyrethroids in the different environmental compartments and to calculate mass balances. Both wetland types demonstrated statistically significant removal of all compounds of interest, with the traditional constructed wetland proving to be a superior treatment option for these hydrophobic contaminants. This result was in agreement with the finding that the compounds under examination were predominantly located in the sediment phase of the constructed wetland, which was not present in the unit process open water wetland.

**279 Why urban and agricultural settings require very different pesticides water quality protection approaches**

*K. Moran, TDC Environmental, LLC*

Pesticides management approaches for water quality protection must address the different upstream pesticide sources, physical environments, and regulatory environments in agricultural settings and urban settings. In agricultural settings, the grower has ultimate control over pesticide applications, often supported by pest control advisors and professional applicators. Growers know the pesticides applied and application timing, can control water use, and have capacity to direct runoff flows from treated fields. In urban settings, thousands of individuals use pesticides in a plethora of ways, sometimes unknowingly (e.g., pesticides impregnated in unlabeled products like paint, roofing, and clothing). Government agencies responsible for urban runoff drainage systems and municipal wastewater (sewage) collection and treatment typically cannot control pesticide use, application location, timing, or discharges in their watersheds and sewersheds. Despite lack of control, under the US Clean Water Act, municipal urban runoff and wastewater agencies (unlike growers) bear legal responsibility for pesticides in urban runoff and wastewater effluent. Pilot projects suggest that treating agricultural runoff containing known pesticides may be technologically feasible, though questions remain about widespread implementation. The outlook for urban pesticides treatment is less promising. With an uncontrolled pesticides mix – and the fact that current use pesticides pass through highly advanced municipal wastewater treatment plants at concentrations exceeding toxicity benchmarks – prospects for treatment as a primary urban pesticide management approach appear poor. Prevention strategies have proven successful in both agricultural and urban settings. Prevention measures occasionally include termination of specific pesticide uses, such as the 1995 California prohibition on sale and use of copper-based root control products in the San Francisco Bay watershed. A more common approach is reducing pesticide runoff load through changes in application rates, locations, and methods, as California Department of Pesticide Regulation and registrants implemented for outdoor structural application methods for pyrethroids (2012) and fipronil (2017). New predictive modeling methods show promise for designing practical prevention-based management practices toward a goal of maintaining pesticide availability for beneficial urban and agricultural purposes without causing water pollution.

## Birds Under Stress: Impacts of Chemical Exposure and Environmental Changes – Part 2

**280 Mercury bioaccumulation in resident and migrant songbirds and effects on body condition**

*J.T. Ackerman, A. Hartman, M. Herzog, US Geological Survey / Western Ecological Research Center*

Methlymercury is a significant risk to environmental health globally. We examined the ecological drivers of methylmercury bioaccumulation in songbirds and its effect on body condition while experimentally removing the potentially confounding and predominant effects of site and habitat. We measured blood and feather mercury concentrations and body condition in nearly 1,200 individuals representing resident or migrant songbirds of 52 species and 5 foraging guilds in the Central Valley of California. Songbird mercury concentrations differed among species, foraging guilds, residency status, dates, and ages, but not sexes. Blood mercury concentrations 1) ranged from 0.003 in house finch to 0.85 µg/g ww in American robin, 2) were 125 times greater in insectivores than granivores and 3.6 times greater in insectivores than omnivores, 3) were 3.3 times greater in summer residents than in migrating songbirds, 4) increased by 25% throughout spring and summer, and 5) were 45% higher in adults than juveniles. Songbird mercury concentrations were negatively correlated with body condition, with blood mercury concentrations decreasing by 44% and 34% over the range of standardized body masses and fat scores, respectively. Our results highlight the importance of foraging and migration ecology in determining methylmercury contamination in birds, and the potential for reduced body condition with methylmercury exposure in songbirds.

**281 Does diet composition or habitat biogeochemistry drive mercury concentration in a threatened wetland bird?**

*L. Hall, I. Woo, S. De La Cruz, US Geological Survey; D. Tsao, California Department of Water Resources; M. Marvin-DiPasquale, US Geological Survey / Water Mission Area; D.P. Krabbenhoft, J. Takekawa, US Geological Survey*

Methylmercury (MeHg) is a globally pervasive contaminant with known toxicity to birds. Variation in MeHg concentrations among individuals of the same species may be driven by variation in the biogeochemical pathways involved in MeHg production or by differences in diet composition among individuals. We examined diet composition, trophic structure, and MeHg biomagnification in the food web of a state-threatened, wetland bird, the California black rail (*Laterallus jamaicensis coturniculus*), along with seven measures of sediment biogeochemistry, to determine whether differences in MeHg concentrations among rails from three adjacent wetlands were driven primarily by differences in diet or habitat biogeochemistry. Black rails were dietary generalists with similar diets among wetlands (percent similarity indices > 72%). The trophic structure of the black rail food web was also similar among wetlands, with trophic magnification slopes for MeHg ranging from 0.18 to 0.28. In sediments, the concentration of MeHg and the ratio of MeHg to total Hg (MeHg/HgT) both differed significantly among wetlands ($p = 0.047$ and 0.021, respectively). Further, we identified five sediment measurements that contributed significantly to a discriminant function explaining differences in sediment biogeochemistry among wetlands: loss on ignition, dry sediment MeHg concentration, MeHg/HgT, the ratio of ferrous iron to total iron, and the concentration of total reduced sulfur. Given the similarities in diet composition, trophic structure, and MeHg biomagnification among wetlands, we concluded that variation in habitat biogeochemistry and associated sediment MeHg production was the primary driver of differences in MeHg concentration among rails from different wetlands.

**282 Is mercury influencing the ability of thick-billed murres to adjust to changing ice conditions in the Canadian Arctic?**

*K.J. Fernie, R.J. Letcher, B. Braune, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; J. Head, K. Elliott, McGill University / Department of Natural Resource Sciences*

The exposure of wildlife to contaminants can result in endocrine disruption and behavioral changes, and such potential changes may occur for Arctic wildlife in conjunction with rapid climate change. Because the endocrine system plays a critical role in allowing animals to respond to environmental stress (e.g., changing ice patterns), endocrine disruption could limit the plasticity of wildlife to respond to climate change. We are examining these interactions with thick-billed murres (*Uria lomvia*) that feed from ice flows and breed in northern Hudson Bay, Canada. Reductions in the availability of ice mean that the birds must spend more energy, obtain less fish, and this can result in poorer reproductive success and chick growth. We seek to determine whether contaminants compound the impacts of climate change on avian wildlife by limiting their ability to respond to changes in ice availability. In 2016 and 2017, the foraging behaviors and movements of 67 thick-billed murres were tracked using GPS-accelerometers, and concentrations of thyroid hormones, corticosterone, mercury (Hg), brominated flame retardants, and per- and poly-fluoroalkyl substances (PFAS) were measured in the plasma of 47 individuals. Levels of PFASs were low, and unrelated to hormones or behavior. However, mercury levels were associated with circulating triiodothyronine ($T_3$) prior to the birds foraging. In contrast to a “medium-ice” year (2016), in a “low-ice” year (2017), the relationship between $T_3$ and Hg was negative. The $T_3$ concentrations of the birds prior to their foraging trips were associated with their foraging behavior; in contrast to 2016, higher levels of $T_3$ were associated with lower diving rates. We found no associations with plasma corticosterone levels. GPS tracks demonstrated that birds from all sub-colonies foraged to the north of the colony during incubation when ice was present, and then moved to forage to the north-west as chick-rearing progressed and ice was no longer present. These results suggest that birds were foraging near regions of floating ice, which may improve foraging success and reduce diving rates. Based on our 2016-18 data, we tentatively conclude that mercury may be influencing the ability of thick-billed murres to adjust to variation in ice cover, and we will further examine that hypothesis in 2018 with a larger sample size and different environmental conditions.

**283 Does calcium concentration in plasma have a protective effect against metal-related oxidative stress? Experiment in great tit nestlings**

*P. Sánchez Virosta, University of Turku / Biology; S. Espín, University of Murcia / Sociosanitary Sciences; S.R. Ruiz, J. Stauffer, M. Kanerva, University of Turku / Department of Biology; A. García-Fernández, University of Murcia / Health Sciences Department / IMIB-Arrixaca – Veterinary Faculty; T. Eeva, University of Turku / Department of Biology*

It has been suggested that calcium (Ca) may provide protection against metal toxicity in the organism. The objective of this study is to explore the effects of Ca levels in the organism and metal exposure on oxidative stress biomarkers in great tit (*Parus major*) nestlings. Great tits were supplemented with Ca (Ca-supplemented group) or not supplemented (Control group) in a metal-polluted and a control area in SW Finland. Feces were collected to measure metal concentrations. We measured an array of oxidative stress biomarkers (GSH, GSH:GSSG ratio, GPx, GST, CAT, SOD, lipid peroxidation and protein carbonylation) in red blood cells and Ca levels in plasma. This study shows that antioxidant levels (tGSH levels, GSH:GSSG ratio, GPx and GST activities) change over the range of metal concentrations depending on the Ca levels in plasma (Fig. 1), suggesting that a balance exists between Ca levels in the organism and the tolerance to metal-related effects. When Ca levels in plasma were higher than 14 mg/dl, increased antioxidants levels were found with increasing metal concentrations in feces. This suggests that birds are able to upregulate their antioxidant capacity to cope with higher metal exposure when Ca in plasma is adequate. On the other hand, when Ca concentrations in plasma were lower than 14 mg/dl, decreased antioxidant levels were observed with increasing metals in feces, suggesting that metals are prone to inhibit the antioxidant system when Ca levels in plasma are low. Thus, Ca concentrations in plasma may have a protective effect against metal-related oxidative stress. Ca scarcity should be considered in future studies evaluating metal exposure and effects in wild birds. *Acknowledgements*: This study was financed by the Academy of Finland (project 265859 to TE), *Societas pro Fauna et Flora Fennica* (to PS-V), University of Turku Graduate School – UTUGS (to PS-V), and *Fundación Séneca* (20031/SF/16 to SE and 19481/PI/14 to AJG-F).

**284 Evaluation of Monotonicity of Concentration Response in Avian Reproduction Studies**

*M. Blickley, Dow Agrosciences / Ecotoxicology; T. Carro, FMC; T.B. Fredricks, Monsanto Company / Global Regulatory Sciences; G. du Hoffmann, EAG Laboratories; K. Henry, NovaSource / Tessenderlo Kerley, Inc. / Ecological Sciences; J.D. Maul, Syngenta Crop Protection / Environmental Safety; S.P. McGee, Bayer CropScience LP / Environmental Health Sciences; S. Mortensen, BASF Corporation; D. Palmer, EAG Laboratories; S. Plautz, BASF / The Institute of Environmental and Human Health; T.A. Springer, Wildlife International, Ltd.*

Avian reproduction tests (OECD 206; OCSPP 850.2300) evaluate effects of dietary exposure to test material for >20 weeks and identify no observed effect concentrations (NOECs). When there is a monotonic trend in response to increasing concentration, the most powerful statistical methods are based on trend tests (*e.g.* Jonkheere-Terpstra (JT) step-down trend test). However, when monotonicity is not evident, investigators often use both trend-based tests and pairwise tests (*e.g.* Dunnett's test (DU)), and make regulatory decisions based on the lowest NOEC. This double testing increases the probability that random differences are declared statistically significant. We evaluated an approach to avoid this double testing. Bootstrap resampling of 36 bobwhite quail reproduction studies and 12 biological measures were used to evaluate the statistical power of tests and the impact of non-monotonicity. Studies were performed in multiple laboratories using a control and 3 exposure groups with 18 pairs of adult quail per group. The resampled data were used to evaluate the performance of DU and JT. When study effects of 20% or less were modeled, random variation alone resulted in ≤1/3 of studies showing greater responses in the low and middle concentrations than both the control and high treatments. When studies with no non-monotonic response pattern were modeled, the power of the JT to detect 20% change is >0.9 for all 12 endpoints except Eggs/Hen/Day (Power ~0.7). Under these circumstances, the JT was slightly more powerful than the DU. If the underlying response pattern is curved so that the responding measure at the highest concentration is reduced by 20% and the mid concentration is reduced by 40%, the power of JT to detect the response in the highest concentration is still >0.9 for all measures except Eggs/Hen/Day Day 14 Hatchling Survivor Weight, and Food Consumption (Power = 0.56, 0.83, and 0.84, respectively); however, the DU is more powerful in detecting effects in all concentrations. We then evaluated the merit of the following rule: 'Use DU test if response measures in low and middle concentrations both exceed those in both control and high treatment groups, otherwise use JT test'. Applying this simple rule resulted in overall power to detect effects equivalent to the DU test alone when the data were non-montonic and to the JT test alone when the data were monotonic, while simultaneously avoiding problems due to double testing.

**285 Interpretation of toxicity data from petroleum dosing studies for integration into avian migration models**

*M.J. Hooper, USGS Columbia Environmental Research Center / Ecology Branch / Restoration Ecology Section; M.L. Wildhaber, USGS Columbia Environmental Research Center / Ecology Branch / Quantitative Ecology Section; M.H. Ziccardi, University of California Davis / Oiled Wildlife Care Network / Karen C. Drayer Wildlife Health Center / One Health Institute / School of Veterinary Medicine*

Assessment of contaminant effects in wild migratory bird populations is generally limited by the time the birds are present in contaminated ecosystems of concern, and end when they fly on to their next destination. However, recent advances in the understanding and modeling of avian migration may provide tools for better prediction of contaminant impacts throughout an extended portion of the annual activity cycle of bird populations. Energetics-based migration models follow bird movements across temporally-relevant, continent-scale maps of food availability while accounting for energy assimilation and expenditure in the modeled birds. Interpreting laboratory and field toxicity findings in terms of their disruption of physiological processes underlying migration could allow prediction of impacts that decrease a bird's ability to maintain energetic conditions that accommodate migration. Toxicological effects that influence migrants' ability to store energy for flight, maintain flight speed, follow migration routes, maintain energetically efficient flight, or carry stored energy during flight could lead to decreased daily travel distances, more frequent refueling stops, and inefficient/erroneous routing to migration destinations. Our current efforts focus on relating previously documented toxic effects of petroleum exposure in birds to endpoints relevant in energetics-based migration models. Previous laboratory and field toxicity studies of birds exposed to oil have shown effects on the hematological, cardiovascular, renal, hepatic, gastrointestinal, endocrine and immune systems. Flight studies have identified impacts on coordination, flight speed and accuracy, energetic expenditures, nutrient assimilation and overall survival. Thermoregulation studies demonstrated loss of body heat with increased nutrient requirements to maintain body temperature. This talk will describe how toxic effects documented in the literature can impact migration-associated physiological and behavioral processes, and thus disrupt migration and threaten survival in exposed birds. Subsequent efforts will focus on incorporation of graded levels of toxic effects into models, as levels of migrant impairment, followed by reassessments of migrant movement, timing, destination acquisition and survival. By understanding the extended ramifications of chemical exposures, we hope to develop more accurate assessments of adverse effects for ecological risk and natural resource damage assessments.

**286 A novel approach to measuring oxidative damage in avian RBCs elucidates an alternative mechanism for cellular damage caused by exposure to crude oil**

*C. Goodchild, Oklahoma State University; S.E. DuRant, University of Arkansas*

Crude oil spills release a variety of contaminants into the environment (e.g., PAHs, toxic metals) and are an ecological hazard to birds and other wildlife. Previous studies in birds have found that exposure to crude oil can cause oxidative damage to red blood cells (RBCs) and hemoglobin (Hb), and may eventually lead to anemia. Although PAHs and toxic metals can damage red blood cells, the mechanism for damage is not always clear. Moreover, common methods for measuring Hb degradation involve using hazardous chemicals. There has been some research in the biomedical field suggesting that oxidation of human-Hb causes degradation of heme subunits and these heme degradation products (HDPs) are fluorescent. In order to better understand the complex relationship between oxidative agents and cellular damage in bird species, we evaluated whether (i) avian RBCs produce fluorescent HDPs, (ii) whether HDPs are linked to RBC membrane integrity, and (iii) whether crude oil exposure increases HDPs. To do so, we collected whole blood from captive zebra finches (*Taeniopygia guttata*) and exposed RBCs in vitro to $H_2O_2$ (model reactive oxygen species). We then measured whether HDPs are correlated with RBC membrane integrity in vivo. Finally, we exposed RBCs in vitro to crude oil and measured HDPs. We found that in vitro exposure to $H_2O_2$ increases HDPs and that HDPs associate with RBC membranes. Additionally, we found that HDPs were linked to impaired membrane integrity in vivo. Furthermore, preliminary data suggest that exposure to crude oil in vitro increases HDPs.

**287 Prioritization of organic contaminants in bald eagles of the upper Midwestern U.S. using the ToxCast High Throughput Screening database**

*S.M. Elliott, US Geological Survey / Upper Midwest Water Science Center; B.T. Route, National Park Service; L.A. DeCicco, US Geological Survey / Office of Water Information; D.D. VanderMeulen, US National Park Service / Great Lakes Inventory and Monitoring Network; S.R. Corsi, US Geological Survey / Upper Midwest Water Science Center; B.R. Blackwell, USEPA / ORD / National Health and Environmental Effects Research Laboratory*

Several organic contaminants, including polychlorinated biphenyls, perfluorinated chemicals (PFCs), polybrominated diphenyl ethers, bisphenol A, and octylphenol have been detected in eaglet plasma collected within and near three national parks in the Midwestern United States. Until recently, there has not been an efficient way to screen these data against toxicity information to provide environmental context or information regarding possible sub-lethal effects. We screened a database of organic contaminant concentrations in eaglet plasma by calculating the ratio of plasma concentrations to concentrations expected to elicit biological responses from the high throughput screening program ToxCast. These ratios, called exposure-activity ratios (EARs), can be used to prioritize contaminants, biological responses, or sites that may warrant further monitoring and research. Bioactivity information was available for 19 of the detected contaminants in eaglet plasma. Most EARs were low ($< 0.1$). However, maximum EAR values were $\geq 1$ for the PFCs, perfluorooctanesulfonic acid (PFOS) and perfluorononanoic acid (PFNA), and bisphenol A in 99, 0.5, and 0.3% of samples, respectively, indicating plasma concentrations were greater than might be expected to elicit some biological response. Genes identified as potentially being affected included those involved in processes such as motor coordination, cardiac functions, behavior, and blood circulation. There was large variability in EAR values across study areas, with larger EARs typically near urban areas. Results from this prioritization assessment can be used to guide future monitoring or research efforts focused on understanding the occurrence and effects of organic contaminants in bald eagles.

## Responsible Chemical Use and Innovative Alternatives for Protecting Infrastructure, Property and Natural Resources

**288 Partnerships for more sustainable chemical use on unpaved roads**

*B.K. Kunz, USGS / Columbia Environmental Research Center; C. Detloff, Midwest Industrial Supply; R.W. Gale, US Geological Survey / Columbia Environmental Research Center; B. Jutz, USFWS*

Chemical treatments on unpaved roads can lengthen road lifespans by stabilizing surfaces and preventing loss of gravel. This protective effect can be particularly beneficial to federal land management agencies that manage extensive networks of unpaved roads with very limited budgets. However, ensuring that chemical treatments are applied in an environmentally responsible way can be difficult. Commercially available products span a huge variety of chemical compositions, including chloride-based, organic petroleum, biobased, synthetic fluid, and electrochemical. Many of these products have little information on ecotoxicity or environmental fate and transport. For some product categories, generating the needed data will require the development of novel testing methods. This presentation describes a collaborative effort among USGS, USFWS, and industry partners to improve the state of environmental knowledge for chemical road treatments. Using a combination of data generated by product vendors for voluntary certification programs (e.g., the former EPA Environmental Technology Verification [ETV] in the United States and Bureau de normalisation du Québec [BNQ] in Canada) and results from a series of laboratory toxicity tests by USGS, project partners were able to identify several products for large-scale field tests at two USFWS refuges. These field tests provided the opportunity to quantify product performance, but also explore novel techniques for evaluating environmental safety under real-world application conditions. In addition, partners developed a two-phase extraction method followed by gas chromatography/mass spectrometry (GC/MS) to detect an environmental signature of a synthetic fluid product that previously had never been tracked in roadside soils. This analytical method has subsequently been adopted by other companies in the private sector. Overall, this project develops a foundation of new environmental data for unpaved road chemical treatments, and provides an example of how cross-sector partnership can help maximize the benefits of chemical treatments while minimizing environmental risk.

**289 Sustainability Implications of Nutrient Removal and Use in Wastewater Treatment Systems**

*M. Sena, A. Hicks, University of Wisconsin – Madison / Civil and Environmental Engineering*

Current use rates of phosphorus have created concern for the sustainability of global phosphate reserves, and research has begun focusing on ways to recover and reuse phosphorus. Wastewater has gained appeal as a viable resource for phosphorus recovery, and the precipitation of magnesium ammonium phosphate ($NH_4MgPO_4$ $6H_2O$),or struvite, has emerged as viable technology. Intentional precipitation of struvite also prevents the unwanted buildup of struvite in other parts of the plant thus reducing and eliminating the expensive maintenance and replacement efforts necessary to remove it. Additionally, struvite precipitation recovers a valuable alternative fertilizer product. However, there are significant energy and chemical requirements necessary for precipitation which raises concern that the overall environmental impacts of this technology are negative.

This research focuses on evaluating the environmental benefits and costs of phosphorus recovery in wastewater treatment by struvite precipitation through a life cycle assessment case study of the struvite precipitation system at a full scale wastewater treatment plant. The considered plant adds magnesium chloride (MgCl?) as a magnesium source and a significant amount of sodium hydroxide (NaOH) for pH control to their struvite precipitation system. Life cycle assessment provides an opportunity to compare the environmental costs associated with the required chemical additions to the benefits from offset production of conventional fertilizers, and conclude weather or not the use of chemicals is justified from an environmental standpoint.

**290 Case Studies on the Use of Chemical Control of Invasive Crayfish**

*A. Allert, USGS / Columbia Environmental Research Center; A.R. Cupp, US Geological Survey / Upper Midwest Environmental Sciences Center; J.A. Stoeckel, Auburn University; K. Knott, Missouri Department of Conservation / Environmental Health*

Integrative pest management programs exploit invasive species life history, target pathways of invasion for invasive species, and use best-available control technologies to combat infestations. Crayfish are critical components of aquatic and terrestrial ecosystem; however, they can be highly invasive. Documented impacts of crayfish invasions include loss of native species of crayfish, amphibians, fish, and birds; alteration of food webs and habitat; and loss of recreation and associated economies. Few chemical control tools are currently available for the management of invasive crayfish. In this work, we investigated the use of cypermethrin, pyrethrin, and carbon dioxide for chemical control of target pathways of new infestations and waterbodies classified as 'non-water bodies' of the state. Laboratory and field investigations tested control of adult Red Swamp Crawfish (*Procambarus clarkii*), White River Crawfish (*Procambarus acutus*), Rusty Crayfish (*Faxonius rusticus*), and Virile Crayfish *(Faxonius virilis*). Research included collaborative interactions with state managers and regulatory agencies to ensure the protection of non-target species and ecosystems, and the registration and permitting for the application of the test chemicals. The results will inform resources managers on best practices for the application of chemicals singly or in addition to mechanical and biological control methods for the control of invasive crayfish.

**291 Promising practices for making informed chemical selections using alternatives assessment**

*A. Nestler, C. Trebilcock, L. Heine, Northwest Green Chemistry*

Alternatives Assessment (AA) provides a framework for informed decision making for intentional chemical applications with transparent analysis of benefits & trade-offs. AA is defined by the Interstate Chemicals Clearinghouse (IC2) as a process for identifying and comparing potential chemical and non-chemical alternatives that can be used as substitutes to replace chemicals or technologies of high concern. AA is an excellent method for identifying the safest solution, be it intentional chemical application or an alternative. In support of WA legislation that phased out the use of copper in recreational antifouling boat paints, the independent nonprofit Northwest Green Chemistry (NGC) recently completed an AA of antifouling technologies, the first AA published following the IC2 AA Guide. NGC is currently engaged in AAs looking at bridge coatings, fluorinated coatings on single-use foodware, and phthalates. This presentation is a retrospective of our AA work, and we will share promising practices, potential pitfalls, and opportunities to influence policy with AA. AA can influence policy and implementation of disruptive solutions. First, the AA recognized the lack of any alternatives for boats with wooden hulls, which may receive an exception. Second, the AA revealed a potential regrettable substitution: Elevated zinc oxide concentrations in copper-free alternatives, which NGC is currently assessing. Third, work with stakeholders provided opportunities for them to meet with representatives of disruptive solutions, such as the Drive-in Boatwash, and explore adoption. From the perspective of promising practices, stakeholder engagement was invaluable. Stakeholders helped identify available alternatives, refine criteria and metrics for product evaluation, identify preferred communication methods, and explain adoption challenges they would face in the transition. Furthermore, involving stakeholders in designing criteria & metrics increases the likelihood that they will accept and support the results of the AA. From the perspective of potential pitfalls, data gaps challenged the AA team in the performance module. The recreational market is not subject to standard test requirements such as those specified for government purchasing, resulting in a paucity of high-quality data. Our report revealed promising practices & potential pitfalls of AA. The AA framework, as a transparent decision-making tool, can be used to clearly communicate with policymakers and the public.

**292 Sustainable Microbial Control Technologies: Preservation of Environmental Resource Quality During Oil and Gas Extraction**

*C. Lehman, Dow Chemical Company / Industrial Biosciences*

As conventional practices for hydrocarbon extraction become less productive, reliance on new sources, including oil sands, tight gas shales, coal bed gas and shale oil is gaining prevalence. Novel extraction techniques, like hydraulic fracturing, are often considered sources of environmental damage and contamination. However, many of these negative effects can be minimized through the strategic targeted use of biocidal products, which allow for optimization of production rates, a reduction in the volume of functional fluids needed, and ultimately a focus on maximizing water preservation and minimizing environmental impact both onshore and offshore. Techniques such as the utilization of biodegradable biocides and diagnostic DNA profiling of target microbial populations can further reduce exposure of terrestrial and aquatic organisms to biocidal actives. Biocides are a highly regulated, well-studied group of chemicals that have been heavily scrutinized with respect to hazard, exposure, and risk mitigation. When this understanding is coupled with risk-based characterization tools, which are scientific criteria that consider both hazard and exposure, biocides can sustainably and effectively control microbial contamination during oil and gas extraction activities.

**293 Bioassay testing applications for products and stewardship**

*P. Arth, Enthalpy Analytical / Nautilus Environmental / Aquatic Toxicology*

Bioassay testing has been utilized to assess the potential toxicity of finished products for many years. Recently, with increasing implementation of the Globally Harmonized System (GHS) of Classification and Labeling of Chemicals, bioassay testing has become a more prominent part of safety data sheet (SDS) preparation. There are additional applications of bioassay testing for products and commercially manufactured goods that can be useful assessment and decision-making tools beyond the commonly recognized framework. Bioassay methods can be a valuable tool for evaluating the potential toxicity of a finished product or individual components, newly developed chemicals, and existing products adapting to changing standards and scrutiny. One such application is the use of bioassays in evaluating ecotoxicological impacts of formulaic modifications. In cases of modifications including the addition of new ingredients or changes to ratios of existing ingredients, bioassays can provide an integrated assessment tool, providing a clearer picture than reliance on literature-based effect levels. Bioassay testing methods can also serve as tools to evaluate the merit and veracity of environmentally-conscious marketing content. Scientists with a deep understanding of these tools and their appropriate use and limitations can support goal definition, testing design, and generation of legally defensible data, which can be incorporated into product development strategies and used as a competitive marketing advantage or a basis for public communication. While some comparative values exist, evaluating products concurrently under identical conditions provides a measure of certainty and data fidelity. Bioassays are also an integral part of the registration process and ensuring this expertise is represented on the registration team helps to ensure that the required data are generated for what is often a complex, lengthy, and resource-intensive process. Given the lack of specific method accreditation, latitude permitted by many test methods designed to evaluate products and chemicals, and overlapping jurisdictional authority and guidance, understanding the potential experimental design challenges associated with a given test article is critical to ensuring an accurate outcome and acceptable data submissions. This is a developing arena for thoughtful application of these tools and an opportunity to prevent environmental impacts and create commercial value for responsible stewardship.

### 294 Towards Sustainable Alternatives for Long-Chain PFAS in Firefighting Foam

*T. Bruton, A. Blum, Green Science Policy Institute*

The use of aqueous film-forming foam (AFFF) in firefighting activities has resulted in environmental releases of poly- and perfluoroalkyl substances (PFAS), adversely impacting the drinking water supplies of communities around the world. Regulatory actions to date have focused on long-chain perfluoroalkyl acids, a subgroup of PFAS including perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA), due to their widespread detection in a variety of matrices including human serum, as well as their demonstrated hazard properties. For example, USEPA negotiated the phase-out of PFOS and PFOA with major manufacturers and issued drinking water guidance for both chemicals. As long-chain PFAS-based firefighting foams have been phased out in the U.S., they have been replaced by AFFF containing short-chain PFAS, despite the similar chemical properties of the two groups and the availability of PFAS-free alternatives. The adoption of foams containing short-chain PFAS rather than fluorine-free foams was driven by multiple factors, some of which are scientific, others of which reflect the interests or values of various stakeholders. This talk will compare and contrast the chemical and toxicological properties of long-chain and short-chain fluorinated surfactants used in firefighting foams, as well as the newer fluorine-free alternatives. The presentation will also explore the environmental and firefighting performance criteria that resulted in the adoption of foams containing short-chain PFAS in the U.S. The evolution of firefighting foam use in the United States will be compared with what has happened internationally. Understanding the full context in which chemicals policy decisions such as this one are made can help scientists and policymakers reduce the potential for regrettable substitutions and find sustainable chemical alternatives.

### 295 Toxicity of wildland fire-fighting chemicals following short, pulsed exposures

*H.J. Puglis, C. Mackey, E.L. Scott, S. Tidwell, R. Calfee, US Geological Survey / Columbia Environmental Research Center*

During the application of fire-fighting chemicals, misapplications can occur such that chemicals are inadvertently applied to the surface of water. The environmental safety of fire-fighting chemicals is most often based on laboratory studies that determine the concentration of chemical lethal to 50% of test organisms over a continuous 96 hour exposure. In contrast, real-world misapplication may result in relatively brief pulsed exposure to an initially high concentration that is progressively reduced as the retardant is diluted and washed downstream. Additionally, pulsed exposure conditions can occur following precipitation events when fire-fighting chemicals applied to the landscape and riparian areas can runoff into waterways. The purpose of the study was to understand the potential toxicity of fire retardants to rainbow trout (*Oncorhynchus mykiss*) after short, episodic exposures. To simulate these short term exposures under different flow scenarios, 30-60 day post swim-up trout were exposed to 1 of 3 different fire retardants, Phos-Chek® MVP-Fx, Phos-Chek® 259-Fx, or Phos-Chek® LC-95A-R, for 15 minutes or 1 hour at two exposure concentrations and then placed in control water to evaluate recovery. The concentrations tested varied for each chemical but include the range of application rates used during fire-fighting activities. After 48 hours in the control water, half the replicates were exposed to the same chemical for the same exposure concentration and duration, and then placed back in the control water. Average mortality was below 20% in all treatments. Survival of the trout varied by number of exposures, chemical tested, and exposure duration, with generally lower survival in treatments experiencing multiple exposures for longer durations. These data can be used by resource managers in selecting products for application to manage any potential risks to aquatic organisms associated with misapplication.

## Incorporating Effect-Based Molecular Assays in Environmental Monitoring and Risk Assessment

### 296 Bioanalytical evaluation of advanced wastewater treatment technologies: A systematic review of existing toxicity data

*J. Völker, NTNU University / Biology; M. Wagner, Norwegian University of Science and Technology / Department of Biology*

Due to the ineffective removal of a broad spectrum of compounds, the discharge of conventionally treated wastewater can negatively impact surface waters and may also affect the quality of raw water for human consumption. Accordingly, several countries either consider or have already started to upgrade their wastewater treatment plants (WWTPs). Full-scale trials conducted at WWTPs demonstrate that technical solutions such as ozonation or activated carbon treatment reduce the load of various selected micropollutants. Nevertheless, an evaluation of wastewater treatment technologies based on few target compounds does not address the large number of micropollutants, their mostly unknown transformation products as well as the combined toxicity of the complex mixtures. To address these limitations, effect-based measurements are increasingly integrated into the evaluation of advanced WWTPs. Bioassays provide a more comprehensive picture of their performance in removing toxicity rather than single chemicals. However, while several reviews of target micropollutant removal by advanced wastewater treatment technologies exist, a systematic review of the removal of toxicity during wastewater treatment is lacking. We, therefore, analyzed the outcomes of existing literature data. Based on our selection criteria, we identified 28 relevant studies containing data of 52 different in vitro bioassays targeting a broad spectrum of endpoints including several endocrine endpoints, induction of xenobiotic metabolism, insecticide and herbicide marker, adaptive stress response, unspecific or baseline toxicity as well as genotoxicity and mutagenicity. Based on this extensive data set, we will give an overview of applied methods, summarize consistent and contradictory results, and highlight research gaps. Moreover, to evaluate the performance of the applied technologies, we will discuss the data set in the context of recently proposed effect-based trigger values.

### 297 Using High-Throughput Approaches to Assess Effectiveness of Wastewater and Stormwater Treatment

*D. Martinovic-Weigelt, University of St. Thomas / Biology; A.C. Mehinto, Southern California Coastal Water Research Project / Toxicology; N. Vinas, US Army / Engineer Research and Development Center; H.L. Schoenfuss, St. Cloud State University / Aquatic Toxicology Laboratory; M. Mills, USEPA / National Risk Management Research Laboratory; P. Edmiston, Wooster Colege / Chemistry; M.L. Ferrey, Minnesota Pollution Control Agency / Environmental Outcomes; D. Fairbairn, Minnesota Pollution Control Agency; C. Lai, University of St. Thomas / Graduate Programs in Software*

We evaluated whether advanced treatment of wastewater (disinfection) and stormwater effluents (iron enhanced filtration) improved removal of contaminants of emerging concern and associated toxicities. Workflow for two studies was similar. Composite water samples were collected from pre-, and post-treated effluents. Their chemical composition and the effects on a variety of molecular targets (25 human nuclear receptors; NRs) and 46 transcription factors/pathways; FACTORIAL platform, Attagene, Inc) were evaluated. Chemistry data was integrated with the publically available toxicity data (ToxCast) to predict whether treatment-related decreases (and increases) in chemical concentrations would “make any difference” to biological receptors. Outcomes of these “in silico” predictions and the empirical in vitro data were compared for consistency.

Control water, and pre- and post- advanced treatment effluents were also used to conduct short-term exposures with fish (wastewater) or *Daphnia* (stormwater); transcriptomic and metabolomics analyses of these samples are partially completed. In silico predictions identified nuclear receptors (well-characterized targets such as estrogen receptor in particular) as the most sensitive and likely to be affected by the exposure; empirical in vitro data supported this prediction. However, in vitro data pointed to additional chemical drivers of toxicity; many of the molecular targets covered by ToxCast were not indicated by predictive toxicology analyses, but were activated in vitro (e.g., peroxisome proliferator activating receptor (PPRE) and glucocorticoid receptor (GR)). In vitro and in vivo toxicity assessments also indicated that treatment-related reductions of parent chemicals are not always paralleled by toxicity reductions. These findings emphasize the importance of characterizing transformation products associated with the wastewater disinfection and stormwater treatment, and highlight the advantages of combining analytical and high-throughput bioeffects approaches to evaluate treatment effectiveness. We are currently integrating analytical chemistry and empirical toxicity data using association rule learning to advance understanding of chemical drivers of wastewater and stormwater toxicity.

**298 Quantitative toxicogenomics methods to predict adverse outcomes in fathead minnow**

*J. Ewald, McGill University / Macdonald Campus / Natural Resource Sciences; O. Soufan, McGill University / Institute of Parasitology; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; J. Xia, McGill University; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences*

Methods of measuring whole-genome gene expression changes, such as microarrays and RNA-sequencing, have great potential for applications in screening and prioritization of environmental contaminants by regulatory agencies. Transcriptomics data can be analyzed to determine whether exposure to a contaminant induces changes in gene expression that have been associated with the development of adverse outcomes. However, the integration of transcriptomics data into regulatory decision making has been hindered by the lack of robust quantitative methods that consistently link well-defined changes in gene expression to apical outcomes. Previous efforts to address this issue have attempted to summarize groups of individual genes in pathways or modules, however changes in the expression of these gene sets have rarely been explicitly linked to apical outcomes. Here, we hypothesize that data-driven gene selection methods will produce toxicity modules with higher predictive power for a well-defined set of apical outcomes than toxicity modules limited to include genes from established molecular pathways. The objective of this study was to define three different sets of 25 toxicity modules for fathead minnow; the first derived from KEGG pathways, the second derived from clusters detected in a co-expression network, and the third derived from a hybrid KEGG/co-expression network approach. The KEGG pathways were chosen based on discussion with toxicology experts and end-users and include 230 individual KEGG pathways from 5 of the 7 KEGG pathway databases. These KEGG pathways form the basis of the co-expression analysis, which is underway. The underlaying dataset being used to build the co-expression network is composed of Agilent-019597 microarray profiles ($n = 304$) from seven previously published studies that measured hepatic gene expression after exposing adult fathead minnow to estradiol, RDX, diethylstilbestrol, PFCs, phenanthrene, and effluent from eight waste water treatment plants. The reproducibility and ability of the three sets of toxicity modules to predict apical outcomes will be evaluated with our own measured RNA-sequencing and apical outcome data from exposure of adult and early-life stage fathead minnow to two model endocrine disrupting chemicals (ethinylestradiol and chlorpyrifos). This study is part of the EcoToxChip project (www.ecotoxchip.ca).

**299 Comparing nanosilver-induced toxicogenomic responses of rainbow trout and white sturgeon using whole transcriptome shotgun sequencing**

*A. Alcaraz, B.K. Eisner, University of Saskatchewan / Toxicology Centre; S. Tang, Chinese Center for Disease Control and Prevention; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre*

Silver nanoparticles (AgNP) is extensively used due to their wide spectrum of antimicrobial properties, but their continuous discharge to surface waters pose risks, particularly towards non-target organisms. In particular, little is known about the toxicological significance of AgNP to fishes native to North America. Typical read-across tests may help informing known toxic responses but may fail to detect other relevant effects, hence, there is a need to generate unbiased information by probing entire biological systems without a priori knowledge of the mechanisms of toxicity. Recent advances in ‘omics technologies have the potential to address this need as they offer high-throughput and cost-effective approaches as they allow for the unbiased examination of patterns of mechanisms of toxicity for use in predictive environmental risk assessment (ERA). Therefore, the objective of this study was to evaluate cross-species responses in native fish species, rainbow trout, *Oncorhynchus mykiss* (RBT) and white sturgeon, *Acipenser transmontanus* (WS), using whole transcriptome-based toxicity pathway analysis. Juvenile RBT and WS were exposed to 10 nM of PVP-coated AgNP in 96h static-renewal system, and sequence-by-synthesis whole transcriptome analysis were used to determine differential gene expression patterns in fish livers. A 0.05 cut-off false discovery rate (FDR) identified differentially expressed contigs between AgNP and control groups. A total of 314 and 415 contigs with gene names were significantly altered in RBT and WS, respectively. Gene set enrichment and pathway analysis using ontologies based on KEGG and GO Consortium showed 23 and 16 pathways perturbed in RBT and WS, respectively. However, only 4 pathways were common between the two species. These pathways include platelet activation, steroid biosynthesis, and integral membrane component and protein processing in ER. On the other hand, using p-Value as less strict parameter in gene selection expanded the list of dysregulated genes and perturbed pathways. Over half of the pathways perturbed in WS overlapped with RBT and were mainly involved in metabolism, biosynthesis, and transport. The results of this study will be compared to apical outcomes assessed in a parallel chronic study, and which will allow the assembly of toxicity pathways across multiple levels of organization with the end goal of identifying molecular markers that are indicative of adverse effects.

**300 Linking transcriptomic responses to apical outcomes of chronic chlorpyrifos exposure in Xenopus laevis**

*N. Baldwin, A. Alcaraz, University of Saskatchewan / Toxicology Centre; M. Brinkmann, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; A. Masse, University of Saskatchewan / Toxicology Centre; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre*

Chlorpyrifos (CPF) is a widely use organophosphate insecticide with extensive occurrence in aquatic ecosystems worldwide. Exposure to CPF is associated with adverse effects in fish including developmental delays and abnormalities, oxidative stress, neurotoxicity, and immunotoxicity. There is much less known regarding the chronic, low-level exposure effects of CPF in amphibians. The objectives of this study were to (1) evaluate apical outcomes of chronic exposure to CPF on the model amphibian (*Xenopus laevis*) and (2) identify and link key molecular response patterns that may be altered during exposure to CPF to these apical outcomes of regulatory relevance. Tadpoles were exposed to CPF (0.5, 2, 8 ug/L, nominal) from early life stage (immediately post-hatch) through to metamorphosis. Individuals were sampled after 96 h and assessed for whole body transcriptome (RNASeq). A subset of tadpoles was then transferred to a flow-through diluter system for exposure to metamorphosis (~ 55 d) and assessed for developmental stage, morphometrics, and organ histopathology. There was no effect of chronic CPF exposure on morphometric endpoints including length, weight, relative liver weight or incidence of malformations. Individuals exposed to 2 ug/L CPF were at a more advanced developmental stage compared to the solvent control. Apical effects will be assessed through histopathology of key organs as well as measures of oxidative stress, immune and apoptotic markers. We anticipate that this work will provide new and valuable amphibian CPF toxicity data to compare to well-studied fish species. We anticipate that this work will identify early life stage critical toxicity pathways that could be used to predict apical outcomes of ecological and regulatory relevance in amphibians, providing an alternative approach in chemical screening. This study is part of the EcoToxChip project (@ecotoxchip).

**301 Coupling animal behavior and gene expression to develop new tools for pharmaceutical environmental risk assessment**

*I. Huang, N. Dheilly, Stony Brook University / School of Marine and Atmospheric Sciences; H. Sirotkin, Stony Brook University / Neurobiology and Behavior; A. McElroy, Stony Brook University / School of Marine and Atmospheric Sciences*

Pharmaceuticals and personal care products (PPCPs) are a diverse group of emerging contaminants that are increasingly detected in surface waters worldwide. While environmental concentrations are typically low, recent research has shown that aquatic organisms residing in contaminated waters bioaccumulate many of these contaminants in various tissues. Despite these measurable body burdens, it is unclear what physiological or ecological impacts PPCPs might have. Long term, sub-lethal effects are difficult to study as many molecular techniques may not be sensitive enough to capture signals of chronic toxicity. Both gene profiling and animal behavior have been proposed to act as sensitive indicators of sublethal toxicity and are both promising methods to approach low level emerging contaminants such as PPCPs. The research we present here couples behavioral analysis with gene expression profiling to develop biomarkers of sublethal antidepressant pharmaceutical exposure and effect. We exposed zebrafish (*Danio rerio*) embryos and larvae to two popular selective serotonin reuptake inhibitor (SSRI) antidepressants commonly found in the environment, fluoxetine (Prozac) and paroxetine (Paxil), and found significant changes in spontaneous swimming behavior and visual motor response at six days post fertilization. RNA-sequencing of individual larval zebrafish brains identified over 1500 genes that were significantly differentially expressed in response to SSRI exposure at concentrations demonstrated to significantly alter swimming behavior. By mining the RNA-seq data, we identified 8 candidate genes that can potentially be used as biomarkers for SSRI exposure and behavioral alteration (fkbp5, nfil3-5, pfkfb4b, ucp2, foxk1, cry1bb, klf9, and stk35). Currently, qPCR assays are underway to confirm that the expression patterns of these 8 biomarker genes are reproducible between different gene expression profiling methods and to test their dose-response and time varying behavior. Further performance tests will include exposing larval zebrafish to wastewater effluent extracts (which contain both SSRIs among other contaminants) to test the efficacy of these biomarkers in realistically complex matrices. Our hope is to integrate molecular biomarkers with other indicators of sublethal toxic effect, like animal behavior, to eventually create predictive models of toxic effect, which will help improve environmental risk assessment and management.

**302 Critical considerations in detecting environmental DNA (eDNA) for enhanced population effects assessment**

*C.C. Helbing, University of Victoria / Biochemistry & Microbiology; J.M. Round, M.J. Allison, L.C. Bergman, University of Victoria*

In toxicological paradigms such as the Adverse Outcome Pathway (AOP), the ultimate desire is to link molecular and organismal indicators to population effects. Evaluation of populations has largely relied upon traditional time-constrained searches that are particularly challenging for species that are cryptic and/or at low densities. The use of environmental DNA (eDNA) detection as a means to assess population distribution and dynamics is becoming increasingly popular as it is more sensitive and cost-and time-effective than traditional methods. eDNA is any trace fragment of exogenous DNA that is released by an organism into the environment. By obtaining a water sample, information about the presence or absence of a species can be determined by measuring the DNA contained within. Targeted species eDNA detection relies upon the use of primers and probes within the context of quantitative real time polymerase chain reaction (qPCR). While considerable thought has been placed on eDNA field collection methods, comparatively little scrutiny has been directed to the qPCR-based tests for which eDNA detection poses unique challenges. Critical considerations include proper primer/probe design and validation for specificity and sensitivity, assessment of DNA sample integrity, and the incorporation of appropriate field- and lab-based controls. Based upon experience from over 40 projects and thousands of samples, these factors will be discussed with solutions for enhancing confidence in eDNA testing methods used in environmental assessment and monitoring.

**303 Mechanistic Tools in Contaminant Monitoring and Risk Assessment--Addressing the Disconnect**

*G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory*

In 1989 the Society of Environmental Toxicology and Chemistry sponsored a Pellston workshop focused on the use of biochemical, physiological, and histological measurements for monitoring the occurrence and effects of contaminants in the environment. The outcome of that workshop stressed the many advantages of these types of mechanistic endpoints (e.g., rapidity/ease of measurement, diagnosis of specific stressors, provision of an early warning system, etc.), and highlighted impediments to their practical adoption and widespread use. Over the past three decades, the scientific community has made huge strides in the ability to generate mechanistic data through advances in areas such as transcriptomics, proteomics, metabolomics, and high throughput (HTP) in vitro testing, but there has been much less progress in terms of routinely using this type of knowledge. So, where have we succeeded and where have we fallen short? Progress has been made in areas such as technical information transfer and the development of approaches for translating mechanistic data into responses meaningful to risk assessments. Other challenges have proven more complex and difficult to address. For example, to employ novel mechanistic tools/concepts, case studies are needed to demonstrate that results/decisions using newer approaches are of a quality comparable to (or better) than current techniques. However, this type of work can be very resource-intensive and the studies difficult to design/interpret with a high degree of confidence. Contributing to the difficulty in demonstrating "success" in case studies is balancing expectations of users with what can be realistically achieved. This presentation will address where we have made progress relative to use of mechanistic data in chemical risk assessment, and identify areas where further work is needed. *The contents of this abstract neither constitute nor necessarily reflect USEPA policy.*

## Interpreting Biological Effects of Metals and Their Mixtures in the Aquatic and Terrestrial Environments

**304 Field biomonitoring and stream mesocosms to evaluate aquatic insect life stage responses to acid mine drainage**

*C. Kotalik, W. Clements, Colorado State University / Fish, Wildlife and Conservation Biology*

North Clear Creek (NCC), Colorado, USA, is severely degraded by dissolved metals and metal oxides, but recent installation of an acid mine drainage (AMD) treatment facility has dramatically lowered metals concentrations. Of particular interest is the trajectory of benthic recovery in NCC following improved water quality. We tested the hypothesis that different aquatic insect life stages, larvae versus winged-adults, would differ in their recolonization propensity. Benthic and emergence sampling were conducted along the NCC metals gradient, and stream mesocosms were used to compare differences in life stage responses to metals under experimentally controlled conditions. Field results showed higher abundances of adults compared to larvae occurring at impaired sites, but higher densities of larvae compared to adults were observed at reference sites. These differences may be the result of source populations from less degraded sites above and below the impaired reaches contributing adults, while conditions at impaired sites still cannot support high larvae densities due to metals inputs from non-point sources and sediments, and poor substrate quality due to historic metal-oxide deposition. Mesocosm results from the dissolved metals (Cu + Zn) experiments revealed greater reductions in larvae abundances at lower metals concentrations compared to emerging adults. However, larvae and adult emergence were similarly associated with the Fe(III) concentration gradient, and adult blackfly emergence was actually more sensitive compared to larval mortality. Differences in response between the metals stressors was likely related to their routes of toxicity, with physiological accumulation of free metal ions associated with dissolved metals, compared to the physical smothering associated with the metal-oxide treatments. Together, these field and mesocosm results suggest that aquatic insects have life-stage-dependent responses to metals, and traditional bioassessments of larvae may inaccurately predict the responses of adults. Aquatic insect adults are critical to benthic recolonization, overall population persistence, and are an important food subsidy to reciprocal terrestrial ecosystems. Field and laboratory approaches should critically evaluate both larvae and adult life stages in order to better understand differences in their responses to AMD exposure and their contribution to benthic recovery.

**305 Using toxicity and amendment studies to inform risk management of containment pond water containing metal mixtures associated with uranium mining**

*J.A. Steevens, J.L. Kunz, US Geological Survey / Columbia Environmental Research Center; R. Gettler, US Geological Survey; D.R. Ownby, Towson University / Chemistry; D. Cleveland, J. Hinck, US Geological Survey / Columbia Environmental Research Center*

The Grand Canyon watershed in northern Arizona, USA contains relatively high-grade uranium deposits associated with breccia pipe formations. The USGS and its partners are currently studying several breccia pipe sites in various life stages (e.g., pre-mining, active-mining, post-mining/pre-reclamation) in order to provide information on the biological and ecological effects supporting risk-based evaluation of breccia pipe uranium mining. Water produced from the mine shaft and runoff from the overburden and ore pile is held in a containment pond. In this work, the *Ceriodaphnia dubia* chronic toxicity bioassay was conducted using waters collected from a pre-mining site containment pond. At the time of water collection, mine shaft drilling was nearing, but had not yet reached the U ore body. The purpose of this study was to determine pond water toxicity to *C. dubia*, identify the metals responsible for any observed toxicity, and to identify potential treatment amendments that could be used to reduce the bioavailability of metals at the site as part of site management. Chemical and bioassay results identified arsenic, cobalt, copper, nickel and uranium as potential risk drivers at the site. Further toxicity studies were conducted for the individual metals (As, Co, Cu, Ni, U) using laboratory waters that mimic pond water quality characteristics. Uranium toxicity in the laboratory water was not observed at the relatively high levels observed in the containment ponds. Geochemical modeling using PHREEQ-C determined that uranium in the waters was likely not bioavailable due to the relatively high levels of calcium, magnesium, and high water hardness but rather a result of elevated As, Co, Cu, and Ni. Batch and isotherm studies using biochar, clinoptilolite zeolite, and glauconite clay amendments were conducted to determine optimal treatment to reduce toxicity by reducing concentrations of free/dissolved metals in the water. Reconstituted metal mixtures in laboratory waters eluted from amendment-packed columns were used to perform the *C. dubia* toxicity bioassay. Results from the toxicity, geochemical modeling, and amendment studies are intended to guide management of metal mixtures in containment pond waters at breccia pipe U mines.

**306 Assessing Bioavailability of Chromium and Nickel in Watercourses, Wetlands, and Floodplains Using Multiple Lines of Evidence**

*S.M. Jones, D.W. Smith, GHD*

Concentrations of chromium and nickel well above default clean-up levels were detected in sediment of a small stream, and wetland/floodplain soils at a Brownfields site in central New York. Sampling of the water column identified very low concentrations of both metals, suggesting that neither metal was likely to be bioavailable or pose risk to ecological receptors despite very high concentrations in bulk sediment and soil. Evaluation of risk to ecological receptors considered five lines of evidence, all of which demonstrated low bioavailability. Porewater in the stream sediments was collected using passive sampling devices (peepers) deployed over a two week period. Concentrations of both metals in porewater were significantly below toxic levels. Risk to the plant communities of the wetlands and floodplain forest was evaluated using two lines of evidence: toxicity tests for germination and emergence of lettuce seeds and vegetative index of biotic integrity (VIBI). The toxicity tests identified a positive correlation between concentrations of chromium and nickel and both test endpoints (i.e., performance increased with increasing concentrations). The VIBI documented healthy plant communities in the wetlands and floodplain. Analysis of earthworm tissue provided a fourth line of evidence to document low bioavailability. Lastly, leaching analyses showed very low leachability of either metal from soils. The results were used to develop site-specific clean-up levels for chromium and nickel for protection of ecological receptors significantly higher than the default levels.

**307 Predicting recovery of aquatic ecosystems after mine reclamation: Mesocosms and in-stream experiments on the North Fork of Clear Creek, Colorado**

*P.J. Cadmus, Colorado Parks & Wildlife / Aquatic Research; A.L. Jefferson, Colorado Parks and Wildlife; C. Kotalik, W. Clements, Colorado State University / Fish, Wildlife and Conservation Biology; J.F. Ranville, Colorado School of Mines / Chemistry and Geochemistry*

The construction of a mine effluent treatment plant in Blackhawk, Colorado, has potential to markedly improve water quality in the North Fork of Clear Creek (NFCC). Upstream of Blackhawk, biomonitoring has shown fish, algae and macroinvertebrate populations to be healthy. However, immediately downstream of the first mine adit aquatic life and function was largely limited by metal pollution. The restoration efforts in Blackhawk present a novel opportunity to develop tools to predict the recovery of aquatic life to the North Fork of Clear Creek and other ecosystems stressed by mixtures of toxicants. Several in-stream experiments were conducted to predict response of fish, aquatic insects and algae. Fish cages across a gradient of pollution were used to predict what species and age classes of trout could survive in NFCC after restoration. Pulse Amplitude Modulated Fluorimetry was used to assess colonization of substrate by algal communities. Metal concentrations were modeled using conductivity and depth data loggers to better capture natural fluctuations in metal concentrations that are often missed by daily or weekly sampling. Fish survival, fish drift behavior and pulse amplitude modulated fluorimetry of periphyton were used across a gradient of metal mixtures to determine at what level of restoration these populations might survive. These tools can be used to predict what species are best for reintroduction to restoration sites and study effects of metal mixtures and fluctuations in an environmentally relevant setting. Results of field studies and mesocosm experiments designed to predict recovery of aquatic life to NFCC often differed from results of laboratory trials. Mesocosm studies using mixtures of toxicants that match NFCC showed response of some aquatic insect and fish taxa below levels predicted by laboratory trials. We found functional responses such as algal respiration and colonization to be more sensitive endpoints than the loss of sensitive species. Even with the reduction in aqueous metals, the indirect effects of iron oxides might preclude colonization of some aquatic life.

**308 Can we model both the bioaccumulation and toxicity of metal mixtures using the same set of parameters in the biotic ligand model?**

*Q. Tan, S. Lu, Xiamen University / College of the Environment Ecology*

The biotic ligand model (BLM) is a useful tool for predicting the bioavailability of metals. It can be used for simulating the effects of water chemistry on either metal bioaccumulation or metal toxicity, and usually separately in different studies. Therefore, even for the same combination of metal and organism, two different sets of BLM parameters would be generated, sharing the same symbols (e.g., KCuBL, KCaBL) but having different values. It has not been tested whether it is possible to obtain universal parameter values for both scenarios. Moreover, there are ongoing efforts to extend BLM for simulating the bioaccumulation and toxicity of metal mixtures, which raise the same question again. In this study, we tested the feasibility of using a single set of BLM parameters to explain both the bioaccumulation and toxicity of mixtures of cadmium (Cd) and zinc (Zn) in an estuarine clam Potamocorbula laevis. The assumptions of our mixture BLM include: (1) Cd2+ and Zn2+ are internalized through the same biotic ligands (i.e., transport sites); (2) Cd2+ and Zn2+ compete with each other during internalization; (3) Internalized Cd and Zn exert toxicity independently. Metal bioaccumulation were quantified using a stable isotope tracer technique; toxicity tests of the Cd-Zn mixtures were conducted in parallel. We found significant interactions between Cd and Zn in both the bioaccumulation experiments and the toxicity tests, consistent with the prediction of BLM. Analyzing the data under the framework of a toxicokinetic-toxicodynamic model using BLM as the toxicokinetic module, we obtained a set of parameter values that could well explain all of the bioaccumulation and toxicity data. The model can be further used to separately quantify the contribution of Cd and Zn to the overall toxicity of the mixture. Through this work, we demonstrated that a unified BLM could be developed to model the interaction between metals in their mixtures.

**309 Predicting nickel and copper toxicity to plants: A meta-analysis**

*Y. Gopalapillai, Environment and Climate Change Canada / Aquatic Contaminants Research Division; P. Wang, Nanjing Agricultural University; B.A. Hale, University of Guelph / School of Environmental Sciences; S. Lofts, NERC Centre for Ecology & Hydrology / Shore Section; P. Koppittke, University of Queensland*

Copper and nickel are both essential trace elements that are used as co-factors for plant enzymes. However, they can result in toxicity above threshold levels, and this effect varies with the nature of the element as well as the plant species. The present meta-study reanalyzes 16 published datasets to investigate if (1) bulk free ion activity ($M2+_b$) or plasma membrane free ion activity ($M2+_0$) best explains observed toxicity to Ni and Cu in variety of plant species and water chemistries; and (2) does a model based on plant metal binding specificity (WHAM-FTOX) or one based on physiological effect at the plant surface (ETM) better explain observed toxicity to Ni and Cu in a variety of plant species. In addition, for the studies that simultaneously measured metal accumulation in the plants, we test whether $M2+_b$, $M2+_0$ or M-FTox predict M-BL, with the assumption that the accumulated metal is equivalent to metal bound to the biotic ligand (M-BL). The present study focused mainly on toxicity datasets from hydroponic plant cultures in order to avoid confounding factors such as inter-correlations among co-variate parameters. The overall goal is to provide the scientific support for existing modeling tools as a cost-effective alternative to mass toxicity testing for the purposes of risk assessment of metal-impacted regions.

**310 Determining Water Quality Threats to *Acropora palmata* Reproduction at Salt River Bay National Historic Park and Ecological Preserve in St. Croix, USVI**

*A. Bayless, University of Charleston, SC / Graduate Program in Marine Biology; C. Woodley, NOAA / NOS / National Centers for Coastal Ocean Science; S.J. Christopher, NIST; R.D. Day, MANTA*

*Acropora palmata* (elkhorn coral) was historically one of the most abundant reef building corals in the Caribbean, but they have declined more than 80% in the last 30 years. In addition to rising sea surface temperatures, ocean acidification, white band disease outbreaks and storms, *A. palmata* and shallow water corals are particularly threatened by anthropogenic pollution and degraded water quality. The surviving *A. palmata* in Salt River Bay National Historic Park and Ecological Preserve (SARI) in St. Croix, USVI have shown reproductive impairment. In contrast, *A. palmata* from Buck Island Reef National Monument (BUIS), northeast of the St. Croix mainland, have a greater reproductive output at most sites. One hypothesis is that poor reproductive condition is attributed to poor water quality in the vicinity of SARI. Sediment and coral biopsies from SARI and BUIS were analyzed for trace elements using ICP-MS to measure metals and elemental proxies of water chemistry parameters. When comparing the SARI population to the BUIS population, boron (B), barium (Ba), and phosphorus (P) were greater in the BUIS *A. palmata* coral skeletons. These elements are proxies of pH, freshwater runoff, and nutrient input, respectively. This analysis infers that nutrient input and freshwater input from the surrounding watershed are not correlated to poor reproductive output in SARI *A. palmata.* In the SARI population lead (Pb), zinc (Zn), and iron (Fe) were significantly greater in *A. palmata* coral skeletons, which indicates greater exposure to anthropogenic pollution and sedimentation in SARI, with concentrations comparable to other studies. Since higher concentrations of Fe were found in *A. palmata* skeletons at SARI, further research should compare sedimentation rates in SARI and BUIS and examine the effects of chronic sedimentation on *A. palmata* reproductive output.

**311 Engineered nanoparticles increase excretion rates of nitrogen and phosphorus by freshwater snails in wetland mesocosms**

*B. Perrotta, Baylor University; M. Simonin, Duke University / Biology; C.W. Matson, Baylor University / Environmental Science; E.S. Bernhardt, Duke University / Biology; R.S. King, Baylor University / Department of Biology*

Wetlands are exposed to engineered nanoparticles through discharge from wastewater and agricultural runoff. We conducted an experiment to examine the combined effects of chronic dosing of nanoparticles and nutrients on wetland food webs. Three levels of nanoparticles (control, gold, copper) were crossed by two levels of nutrients (ambient vs. chronic nutrient dosing) in 18 outdoor wetland mesocosms. We measured the rate of excretion of nitrogen (N) and phosphorus (P) in freshwater snails after six months exposure to chronic nanoparticle and nutrient dosing. Ten *Physella acuta* snails were collected from each mesocosm. Individual snails were placed into tubes containing filtered, control mesocosm water. Snails were incubated for 95 ± 0.5 minutes (mean ± SE). Excretion of N and P was significantly higher in all nutrient-dosed mesocosms than ambient nutrient controls. However, under ambient nutrient levels, gold and copper nanoparticle treatments each significantly increased snail N and P excretion. These results imply that nanoparticles may interfere with snail digestion and nutrient assimilation, particularly under low nutrient conditions.

## Integrating Big Data Into the Bigger Picture

**312 How to develop targeted eDNA sequencing tools for geographical mapping of aquatic species: A case study**

*J. Shaw, CSIRO / Land and Water*

It is not financially or spatially plausible to restore degraded habitat zones along entire river systems, but instead restoration efforts must be appropriately-geographically focused for species or communities of interest. To do this successfully, it is critical that information regarding the specific locations of taxa is obtained. Although current survey tools such as traps and nets provide useful demographic information, they are not ideal for large-scale 'screening' operations, as they typically involve significant time and effort to place nets out, collect them in, and to taxonomically identify captured species. This greatly limits the number of sites that can be searched per funding and time allocations. Further, for endangered species, capture rates are low and only further increase habitat degradation, vulnerability to predation, and detrimental health impacts to individuals. Therefore, alternative rapid and cost effective tools such as Environmental DNA (eDNA) sequencing are valuable for geographically mapping the biodiversity of vast river systems. The Murray–Darling River Basin (MDB) is a river system covering one seventh of mainland Australia, maintaining over 2,520 kilometres of diverse riverine habitats. However, fish species endemic to the MDB have undergone severe population declines due to habitat degradation, pollution, and pressures from alien species. This study resulted in the development of eDNA sequencing-based screening tools for both fish biodiversity and also for species-specific targeting of endangered taxa. We enabled the locations of small fragmented populations to be geographically mapped using these rapid and cost effective tools, and this information will assist with the selection of species-specific target areas for habitat restoration in the MDB.

**313 Multi-level effects of chemical oil dispersant and CEWAF exposures in developing mahi-mahi embryos**

*J. Greer, UCR / Environmental Sciences; C. Pasparakis, Rosenstiel School of Marine Sciences / Marine Biology and Fisheries; M. Grosell, University of Miami / Marine Biology and Ecology; D. Schlenk, University of California-Riverside / Department of Environmental Sciences*

The Deepwater Horizon (DWH) oil spill released more than 200 million gallons of crude oil into Gulf of Mexico waters in 2010. Nearly 2 million gallons of the chemical dispersant Corexit were deployed as a surfactant to expedite microbial degradation of the oil. The timing of the DWH spill coincided with the spawning season for many commercially and economically important marine fish species, including mahi-mahi (*Coryphaena hippurus*). Thus, early life stage fish were likely exposed to oil, as well as varying mixtures of oil and dispersant. Cardiotoxicity, craniofacial malformations, and reduced swimming performance have been observed following oil exposure in mahi-mahi. Other pathways of oil toxicity have been uncovered via RNASeq, including central nervous system degeneration. Sublethal effects of Corexit exposure alone and in combination with oil (CEWAF) are less studied. To better characterize the impacts of CEWAF on mahi-mahi development, mahi mahi embryos (~6 hpf) were exposed to one of three Corexit concentrations or CEWAF with varying Corexit concentrations for 48 hours. The surviving embryos were collected and transcriptomes assessed with RNASeq. Corexit exposure induced80% across all concentrations. Corexit exposures and controls also formed a tight cluster in a principal component analysis. These data suggest that Corexit exposure alone may not have a significant effect on embryonic development in mahi-mahi. CEWAF preparations induced 3010, 2379, and 2565 differentially expressed genes in low, medium, and high Corexit concentrations, respectively. Percent survival was ~65% in CEWAF preparations, a significant decline compared to controls ($p< 0.05$), but not significantly different than Corexit alone. Importantly, varying Corexit concentration in CEWAF exposures did not significantly affect percent survival. These results indicate that Corexit addition alone may not alter overall mortality at this stage, and it does not greatly impact the number of differentially expressed genes of oil exposed mahi-mahi embryos. Ongoing pathway analyses will determine whether CEWAF altered previous HEWAF predictions based on RNAseq data. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER).

**314 Transcriptomics to behavior- What the Deepwater Horizon spill can teach us about fish vision**

*J.T. Magnuson, University of California-Riverside / Environmental Sciences; G. Xu, McGill University / Department of Environmental Sciences; D. Schlenk, University of California-Riverside / Department of Environmental Sciences; A.J. Khursigara, The University of Texas at Austin / Marine Science Institute; E.B. Allmon, Purdue University / Department of Forestry and Natural Resources; A. Esbaugh, University of Texas Marine Science Institute / Department of Marine Science; R.M. Heuer, University of Miami / Marine Biology and Ecology; J.D. Stieglitz, RSMAS University of Miami / Marine Biology and Ecology; M. Grosell, University of Miami / Marine Biology and Ecology; A.P. Roberts, University of North Texas / Advanced Environmental Research Institute*

The *Deepwater Horizon* (DWH) oil spill released millions of barrels of oil into the Gulf of Mexico, coinciding with peak spawning periods of ecologically important fish species, such as the mahi-mahi (*Coryphaena hippurus*) and red drum (*Sciaenops ocellatus*). Polycyclic aromatic hydrocarbons (PAHs) present in DWH oil has been shown to cause developmental malformations in fishes, with more pronounced effects during early life stages. Mahi-mahi and red drum embryos were exposed to slick oil and assessed for visual function using transcriptomics, histology, and visually-mediated behavioral assays. The major processes impacted following exposure to environmentally relevant PAH concentrations, as determined through RNAseq and qPCR, were associated with eye formation and phototransduction, with a downregulation of genes important in eye development and function. Using the flicker-fusion principle to monitor an optomotor response and histological analysis, oil-exposed larvae exhibited a reduced optomotor response with a reduction in retinal layers and neuronal connections that play an important role in visual function and image processing. The present study provides evidence that weathered crude oil affects the visual system in developing larval fish, and relates oil-induced transcriptomic effects to histological and behavioral-level endpoints. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER).

**315 Linking transcriptomics with metabolomics to assess the mechanism of action of naphthalene sulfonate in the Western clawed frog**

*S.J. Wallace, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement; A. Leclerc, A. Shenfield, Queens University; R.S. Prosser, University of Guelph / School of Environmental Sciences; S. de Solla, Environment Canada / Ecotoxicology and Wildlife Health Division; V. Balakrishnan, Environment and Climate Change Canada / Aquatic Contaminants Research Division; V.S. Langlois, INRS / Centre Eau Terre Environnement*

Naphthalene sulfonic acids are priority chemicals being assessed by the Government of Canada's Chemicals Management Plan that act as dispersants and are components used in industrial lubricants, corrosion inhibitors, and commercial jet fuels. However, little is known about their toxicity to aquatic organisms. Western clawed frogs (*Silurana tropicalis*) were exposed to sand spiked with i) 17 – 1,400 µg/g calcium dinonylnapthalene sulfonate (CaDNS) from egg to larvae and with ii) 25 µg/g CaDNS from egg until the peak of metamorphosis. In the larval experiment, the 100 µg/g CaDNS spiked sand only yielded 14 ng/mL CaDNS in the water column, but yet induced deformities in 98% of the larvae. Transcriptomic analyses revealed over 3,600 genes were differentially expressed in embryos exposed to CaDNS, including biological processes and molecular functions related to cellular structural development. Targeted and untargeted metabolomic analyses (496 analytes) showed a decrease in essential amino acids and metabolites related to muscle movement. There was a decline in the reduced and oxidized forms of glutathione metabolites, which corresponded with a decrease in the transcript level of the genes of the enzymes responsible for converting the two (glutathione reductase and peroxidase). In addition, chronic exposure to CaDNS increased the time to metamorphosis, decreased body size, and decreased gene expression related to thyroid hormones. Combining results from transcriptomics and metabolomics can provide a robust approach to demonstrate the manifestation of the effects of contaminants at multiple levels of organization to work towards developing an adverse outcome pathway.

**316 Seeing the forest through the trees: Integrating multi-'Omic datasets with chemical monitoring data and higher level effects**

*D. Simmons, Denina Simmons Scientific Consulting / Biology*

Currently, collaboration between multiple stakeholders and research teams is necessary for conducting multi-omics that are integrated into environmental monitoring studies. A high level of organization and coordination is required during the experimental design and preparation stage to ensure that all samples are collected appropriately, and that information can be tracked among samples and between different teams with ease. In particular, tissue type, exposure duration/season of field collection, sample storage, and labeling can present challenges not typically encountered within a single 'Omics study or a traditional ecotoxicology study. Post-data acquisition, there are separate statistical challenges involved in the integration of different data types, including data format, scaling, and normalization. Finally, biological interpretation of large environmental datasets is the final bottleneck, and normally requires a high level of expertise in using multiple bioinformatics tools and a sophisticated understanding of environmental effects at different levels of organization in order to ensure that the big picture is captured and does not become obscured by the enormous amount of detail – most of which is caused by simple biological variation. In this presentation, portions of data from three different integrated multi-omics ecotoxicology studies will be shared to illustrate the challenges (and successes) of integrating 'Omics studies with more traditional endpoints.

**317 Ecotoxicological effects of metformin and guanylurea on Japanese medaka (*Oryzias latipes*)**

*E. Ussery, University of Ontario Institute of Technology / Biological Sciences; K.N. Bridges, State of Alaska Division of Public Health / Environmental Public Health; D. Simmons, Denina Simmons Scientific Consulting / Biology; B.J. Venables, University of North Texas / Advanced Environmental Research Institute; Z.P. Pandelides, University of Ontario Institute of Technology; J. Guchardi, University of Ontario Institute of Technology / Faculty of Science Aquatic Toxicology; D.A. Holdway, University of Ontario Inst. of Tech / Science*

In recent years, environmental research has recognized the occurrence and fate of pharmaceuticals in the aquatic environment as an emerging issue in aquatic toxicology. One of the most prevalent contaminants is the type-2 diabetic drug, metformin. Metformin has been measured in the ng-µg/L concentration range in surface waters and wastewater effluent. As >90% of metformin is metabolized into guanylurea during the waste water treatment process, its metabolite guanylurea is found in the µg/L concentration range, thus of major concern. Our recent research shows that male Japanese medaka (*Oryzias latipes*) exposed to metformin and guanylurea from embryo through 28 days post hatch have a significant decrease in length and wet weight when compared to control fish. Metabolomics and proteomics are emerging as an efficient method for understanding sub-lethal effects on organisms by assisting in determining the biochemical mode of action in response to exposure to a particular contaminant. This current study showed significant changes in the metabolome of 28 day old male medaka exposed to metformin and guanylurea, indicating significant dysregulation in fatty acid and lipid metabolism including metabolites associated with cellular energetics and central nervous system health. Additionally, expression of critical genes involved in lipid metabolism were also significantly affected. Proteomic effects on early-life stage medaka exposed to metformin and guanylurea will be explored.

**318 Metabolomic analysis of juvenile Chinook salmon exposed to a mixture of pharmaceuticals and personal care products in the lab and field**

*J. Meador, NOAA Fisheries / Ecotoxicology and Environmental Fish Health Program*

A recent study assessed the occurrence and concentrations of a select number of pharmaceuticals and personal care products (PPCPs) in estuary water, effluent, and juvenile Chinook salmon (*Oncorhynchus tshawytscha*) from one reference estuary and two WWTP-impacted estuaries in Puget Sound, WA, USA. We also conducted a laboratory study with fish dosed for 32 days with 16 of the most common contaminants of emerging concern (CECs) detected in feral fish. Data from a recent study provide support for metabolic disruption based on a limited suite of blood chemistry parameters (Meador et al. 2018). The results from that study were further explored with metabolomics to provide a more complete characterization of metabolic impairment. Metabolomics is the evaluation of small endogenous molecules and products of metabolism such as amino acids, fatty acids, nucleotides, and other important compounds in physiological pathways. These data where subjected to multivariate analysis to test for differences between sites and to explore pathway alteration. A targeted metabolomic approach was used to assess the levels of 219 analytes in replicate plasma samples for fish from the field and the lab study. Additionally, an untargeted metabolomic approach was used to examine for metabolite differences in replicate liver samples from these fish as a separate line of evidence. The untargeted approach identified approximately 2,000 unique molecules and these data support the results obtained with the targeted values for plasma samples. A high percentage of metabolites from both the targeted and untargeted approaches were significantly different between fish from the reference estuary compared to fish from the two WWTP-impacted sites. The two impacted sites exhibited similar responses for a number of compounds and were in agreement when metabolites were expressed as fold-change values compared to reference site fish. The altered metabolomic profile is useful as an early indicator of metabolic stress, even though organismal characteristics (lipid content and condition factor) were not different among sites. Evidence of metabolic disruption was also observed in juvenile Chinook salmon exposed in the laboratory to a limited mixture of CECs for both plasma and liver samples. These metabolomic data allowed us to explore altered or impaired metabolic pathways, which may help identify the most important CECs responsible for the observed responses and possibly mechanisms.

**319 Enhancing the utility of the ECOTOX knowledgebase via ontology-based semantics mapping**

*K.A. Fay, General Dynamics Information Technology; C. Elonen, USEPA / ORD / NHEERL; D.J. Hoff, USEPA / ORD / Mid-Continent Ecology Division; M. Skopinski, A. Pilli, General Dynamics Information Technology; R. Wang, USEPA / Exposure Methods and Measurements Division; C. LaLone, USEPA / Mid-Continent Ecology Division*

The US Environmental Protection Agency's Ecotoxicology (ECOTOX) knowledgebase contains more than 30 years of reported single chemical toxicity effects data on aquatic and terrestrial organisms. Approximately 900,000 test results covering more than 11,000 chemicals and 12,000 species are available in ECOTOX. While the database is currently used by many sectors for a variety of purposes, a future goal is to allow for computational modeling of the data to identify novel adverse outcome pathways and networks, and assist in predicting chemical hazard and species sensitivity. One obstacle is that ECOTOX captures the study designs and test results using author-reported descriptions, resulting in more than 4000 codes. Relationships among these codes are often not apparent in the current design (e.g., aryl hydrocarbon hydrolase and cytochrome P450 1A), and some codes are uniquely specific to the study of its derivation (e.g., 3rd generation male). To enhance the query capability of the data within and external to the ECOTOX knowledgebase, and to prepare for future computational functionality, the ECOTOX codes were mapped to existing biological ontology classes. A Java-based lookup tool was developed using the ontology browser BioPortal (https://bioportal.bioontology.org/) REST API to semi-automate the code mapping. This tool was designed to allow for batch processing and to make use of BioPortal's annotator and recommender functions so that all ontological class identifiers relevant to a particular ECOTOX term would be returned and specific ontologies recommended. Using this approach, the majority of the ECOTOX codes were mapped to ontological class identifiers; some terms required multiple identifiers to properly describe them. A set of unmapped terms unique to the ECOTOX database were also identified. Manual curation of the results was also conducted to ensure proper context for the mapped classes.

## Immunoanalytical Technologies: Development and Applications for Environmental Monitoring

**320 VHH antibodies are versatile tools for the analysis of environmental chemicals.**

*N. Vasylieva, UC Davis / Entomology; Z. Li, C. Zhang, D. Li, B. Barnych, University of California, Davis; B.D. Hammock, University of California, Davis / Department of Entomology & UCD Comprehensive Cancer Center*

Bio-recognition elements are the key to affinity based bioanalytical technology. Nanobodies obtained from phage display technology have drawn much attention in recent years due to their promising advantages in gene engineering. Camelid single domain antibodies (sdAb, nanobody or VHH) are increasingly popular due to their small size, high stability, ease of genetic manipulation, and ability for continuous reproducible manufacture. We have shown their use in assays for detection and quantification of pesticides, their metabolites and industrial chemicals that are comparable to polyclonal or monoclonal antibody-based assays. Several examples of nanobody-based immunoassays for chemicals will be presented, as well as their alternative applications for exposure monitoring and environmental analysis.

**321 Development of a Fusion Protein and Its Application in a Highly Sensitive Direct Competitive Fluorescence Enzyme Immunoassay for Detection of 3-PBA**

*J. Huo, University of California, Davis / Agricultural University of Hebei; X. Cui, W. Ren, University of California, Davis / Entomology and Nematology; D. Li, Z. Li, UC Davis; N. Vasylieva, UC Davis / Entomology; B. Barnych, University of California, Davis; B.D. Hammock, University of California, Davis / Department of Entomology & UCD Comprehensive Cancer Center*

Pyrethroids are one of the most largely used insecticide classes in the world. It is important to develop sensitive and rapid analytical techniques for environmental monitoring and assessment of human exposure to these compounds. Because most pyrethroids contain a phenoxybenzyl group and 3-PBA is a human urinary metabolite of pyrethroid insecticides and can be used as a biomarker to monitor human exposure to these pesticides. A rapid and sensitive direct competitive fluorescence enzyme immunoassay (dc-FEIA) for 3-Phenoxybenzoic acid (3-PBA) based on a nanobody (Nb)-alkaline phosphatase (AP) fusion protein was developed. The VHH (variable domain of heavy chain antibody) gene of 3P5ThC12 was subcloned into the expression vector pecan45 containing the AP double-mutant gene. The 3P5ThC12-AP construct was transformed into *Escherichia coli*, and soluble expression in bacteria was confirmed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis. Both the Nb properties and AP enzymatic activity were validated by colorimetric and fluorometric analysis. The 50% inhibitory concentration and the detection limit of the dc-FEIA were 0.082 and 0.008 ng/mL, respectively, with a linear range of 0.015−0.447 ng/mL. This assay was compared with LC−MS/MS, and the results indicated the reliability of Nb-AP fusion protein based dc-FEIA for monitoring 3-PBA in urine.

**322 Development of immunoassays for mushroom toxins**

*C.S. Bever, USDA-ARS; B. Barnych, University of California Davis; L. Stanker, USDA-ARS*

Some of the poisonous and deadly mushrooms contain identified toxic components, such as amatoxins or orellanine. A single mushroom can contain enough toxin to make a person very ill and can be potentially fatal. Our goal is to develop antibodies to these toxins, in an effort to make immunoanalytical methods to detect them. Although the toxin itself is too small to be immunogenic, these small toxins can be covalently linked to larger protein carriers in order to render them immunogenic. Both toxins were linked to carrier proteins using unique conjugation strategies and confirmed by matrix assisted laser desorption/ionization mass spectrometry (MALDI-MS) analysis. Antibodies were raised to both conjugates and characterized by competitive enzyme-linked immunosorbent assay (ELISA). In the case of amatoxins, an immunoassay was developed that could sensitively detect α-, b-, and γ-amanitin down to 1 ppb (ng/mL). In addition, toxin detection from mushroom samples was demonstrated using mushrooms known to contain amatoxins. Further assay characterization and formatting is underway to enable rapid detection of these harmful toxins.

**323 Quantifying amatoxin residues via a nanofibrous portable immunoassay**

*C. Zhao, UC Davis / Agriculture and Environment Chemistry; Y. Si, UC Davis / Department of Textiles and Clothing; B. Pan, UC Davis / Department of Agricultural and Environmental Chemistry; C.S. Bever, USDA; G. Sun, UC Davis / Department of Agricultural and Environmental Chemistry*

Enzyme-linked immunosorbent assay (ELISA) is one of the widely used methods for sensitive and quantitative toxin detection. However, conventional ELISA is instrument-dependent, time-consuming, and complicated-operating, limiting its application in non-laboratory regions. Here, we develop a portable, convenient and high-sensitive biosensor by applying indirect competitive immunoassay on nanofibrous membranes. Taken the advantages of the ultrahigh surface area of nanofibrous membranes, biosensor sensitivity was improved by increasing antibody loading amount. Thus, colorimetric signal form trace analytes can be observed by naked eyes within 30 mins, and quantitative analysis can be further achieved by scanning the membrane with a smartphone. The Limits of detection (LOD) was achieved at 0.1ppb for amatoxin, which is comparable to conventional ELISA using a specialized instrument. Thus, the portable nanofibrous biosensor has the potential to be applied in a wider field.

**324 A utility evaluation of an antibody-based biosensor for detection of 3 – 5 ring Polycyclic Aromatic Hydrocarbons**

*C. Prosser, ExxonMobil Biomedical Sciences, Inc.; M.A. Unger, Virginia Institute of Marine Science / College of William and Mary / Aquatic Health Sciences; T. Parkerton, ExxonMobil Biomedical Sciences Inc. / Toxicology & Environmental Science; D. Letinski, A. Bleich, ExxonMobil Biomedical Sciences Inc*

Polycyclic Aromatic Hydrocarbons (PAHs) represent a ubiquitous contaminant in the environment stemming from both petrogenic and pyrogenic sources. PAHs also represent a hazardous portion of complex petrogenic sources and as such are of great interest to regulators during remediation activities. Traditional extraction and quantification of PAHs can be both costly and time consuming requiring large amounts of hazardous solvents and may result in weeks of lag time before a large number of samples can be analyzed. Emerging technologies using monoclonal antibodies capable of binding 3 – 5 ring PAHs may dramatically reduce both cost and time, while subsequently increasing the number of samples that can be run. When combined with fluorescence emission/detection, the biosensor is capable of quantifying total alkyl and parent 3 – 5 ring PAHs in a sample. Additionally, this method requires no sample clean-up or treatment with raw water samples run directly. While unable to differentiate individual molecules, this method can be used to screen potential samples for future analysis, and/or assess the fate and transport of PAHs within contaminated areas. Previous work with this technology has demonstrated the ability to quantify to the sub-ppb level. This method has great potential within industry to analyze and/or monitor samples from complex field conditions. For three years ExxonMobil has been collaborating with the Virginia Institute of Marine Science to evaluate the utility of this antibody as a quantification tool across an array of applications. Previous work has validated the sensor as accurately detecting PAH concentrations from a number of different Water Accommodated Fractions (WAFs) that are used in acute and chronic toxicity tests. Additionally, the biosensor has been used to monitor PAH concentrations from samples taken during a simulated sub-surface oil release at the he National Oil Spill Response Research & Renewable Energy Test Facility (Ohmsett facility, Leonardo NJ). Additional work has been done to evaluate the bioavailable fraction of PAHs in sediment pore water as a more accurate predictor of toxicity as compared to traditional whole sediment concentrations. Here we will discuss some of the past work we have completed with the antibody as it pertains to the environmental fate, transport and toxicity in addition to future opportunities this technology may provide.

**325 Antibody-based biosensor technology as a tool for near real-time quantification of PAH contamination in bivalves**

*K. Prossner, M.A. Unger, G.G. Vadas, Virginia Institute of Marine Science / College of William and Mary / Aquatic Health Sciences*

At sites contaminated with polycyclic aromatic hydrocarbons (PAHs) sessile filter feeders such as bivalves are particularly susceptible to accumulation of these contaminants. During a potential PAH-contamination event such as an oil spill, quick assessment of seafood safety is important to stakeholders and resource managers. Traditional quick response methods such as sensory analysis (e.g. sniff testing) of seafood are often unreliable, non-quantitative and met with distrust by the public. More reliable PAH quantification methods such as conventional GC-MS analyses take several weeks and are expensive. A new, highly sensitive, rapid (minutes) antibody-based biosensor method has been developed to measure total PAH concentrations in individual bivalves using small volume (1-2mL) aqueous samples. Hydrophobic PAHs exist in different phases in the environment (e.g. dissolved aqueous phase and bound-organic phase). At dynamic equilibrium, the concentrations of PAHs in different phases are proportional to each other via partition coefficients, or equilibrium constants. This implies that an unknown concentration of PAHs in one phase can be calculated from another by a simple ratio based on the partition coefficient for the two phases. In this study, bivalves were collected from sites in the Chesapeake Bay with varying levels of PAH contamination and were analyzed by biosensor and conventional GC-MS methods. PAH concentrations in bivalve mantle fluid analyzed by the biosensor correlated well with PAH concentrations analyzed by solvent extracted GC-MS methods indicating that equilibrium within the aqueous and lipid phases in oysters is occurring and whole animal concentrations can be predicted reliably. The biosensor method shows great promise to rapidly and accurately predict PAH concentrations in the bivalve lipid-bound phase based on dissolved PAH concentrations measured in bivalve mantle fluid (e.g. aqueous phase). Biosensor technology could serve as an important tool for rapid evaluation of PAH-contaminated seafood in time-sensitive situations such as oil spill response. This technique is also significantly cheaper than conventional methods on a per sample basis. Further applications may include rapid and economical mapping of background PAH levels in the Chesapeake Bay or Gulf of Mexico oyster reefs to better characterize effects of spill events.

**326 Development of a nanobody and Urchin-like gold nanoparticle immunochromatographic strip test for rapid detection of aflatoxin B1 in grains**

*W. Ren, University of California, Davis / Nanchang University / Department of Entomology & UCD Comprehensive Cancer Center; Y. Xu, Y. Li, Z. Huang, Z. Tu, Nanchang University / College of Food Science; B.D. Hammock, University of California, Davis / Department of Entomology & UCD Comprehensive Cancer Center*

An immunochromatographic strip (ICS) using urchin-like gold nanoparticles (UGN) and nanobodies for sensitive detection of Aflatoxin $B_1$ ($AFB_1$) was developed to meet the requirement for rapidly monitoring AFB1 in grain samples. The detection limit of $AFB_1$ in a grains matrix was 0.5 ng/mL, which represents a Sixteen-fold increase in sensitivity over conventional Enzyme-linked immunoassay. Analysis of $AFB_1$ in grain samples revealed that data obtained from the ICS were in a good agreement with those obtained from HPLC and ELISA. This qualitative test based on the visual evaluation of results did not require any specialized equipment and the assay time was less than 10 min, which is suitable for rapid on-site testing of $AFB_1$ in grains samples.

**327 Direct and rapid detection of okadaic acid from crude shellfish extracts with a portable multi-channel surface plasmon resonance (SPR)-based biosensor**

*S.D. Soelberg, N. Nguyen, University of Washington / Medicine; K. Campbell, C. Elliott, Queens University of Belfast / Institute for Global Food Security; J.M. Hungerford, FDA / Applied Technologies Center, Bothell, WA; C.E. Furlong, University of Washington / Medicine / Div. Medical Genetics*

The numerous cases of toxin-associated illnesses from consumption of contaminated shellfish illustrate the need forrapid, regenerable and sensitive detection assays for a wide variety of these aquatic toxins that can be easily used on-site. We describe here a buffered methanolic extraction protocol for the detection of levels of the diarrhetic shellfish toxin okadaic acid (OA) below the guideline levels in shellfish samples using a portable surface plasmon resonance (SPR) sensing system. The gold sensor surfaces were coated with BSA conjugated to OA with the standard EDC/Sulfo-NHS coupling protocol. The assay was run in competitive mode where an analyte-free solution of anti-OA antibodies was run through the system to establish a “no-analyte” rate of antibody binding. The presence of analyte in solution decreased the binding rate proportional to the concentration of analyte. Following each detection event, the bound antibodies were removed by automatically flowing a regeneration buffer (220 mM NaOH/20% acetonitrile) over the sensor surfaces followed by an automatic rinse with running buffer. Reagent preparation involved coupling the antibodies to immunomagnetic nanobeads that allow for a rapid purification and concentration of the toxin from the shellfish matrix. Immuno-nanobeads also increase the SPR signal dramatically over antibody alone. This increase in total signal also increases the sensitivity of detection by approximately 50-fold to a limit of detection below 0.1 ng/ml. This portable detection protocol was designed for ease of use at harvesting sites by injecting diluted extraction buffer or bead washed sample directly into the detector system. Employing the “dilute and shoot” or nanobead approach avoids the more complex evaporation and reconstitution steps. The detection system is capable of multiplexing to include the simultaneous detection of multiple toxins from a single sample injection. In addition to development of the detection assay, recent advancements have improved the performance and portability of the SPR detection sensor including flow cell improvements, lowering power consumption for battery operation, and reduced instrument size for improved portability. These developments combine to produce a portable system for use in on-site toxin detection protocols. The system is also adaptable for use in autonomous multiplex monitoring of several toxins or toxin congeners simultaneously as well as other environmental hazards.

# Chemical Mixtures in Urban Systems – Screening and Prioritization of Emerging Contaminants

### 328 Development of Target Screening Method for 489 Polar Pollutants by LC/QTOF-MS

K. Kadokami, *The University of Kitakyushu*

Highly efficient analytical methods are necessary to determine the concentrations of the large number of chemicals used in the society that end up in the environment for understanding their potential environmental impacts. Many of these chemicals are best determined using liquid chromatographic mass spectrometric methods (LC/MS). In the present study we developed new target screening method for 489 polar substances, including 298 pesticides and 162 PPCPs, in water samples by LC/QTOF-MS. A water sample (200 ml) spiked with surrogates is first extracted by tandem SPE (Waters HLB-plus and AC-2 cartridges), and then the extract is concentrated to 0.5 ml. Finally, after adding internal standards, the concentrate is screened using a LC/QTOF-MS (Sciex X500R) by positive ESI and Swath. Results of recovery tests using purified water at two concentrations (0.5 and 0.05 ug/L) showed average recoveries of 87.0 and 87.4% (RSD, 9.4 and 9.0%, respectively). Limits of detection of most targets are below 1 ng/L, which is sufficient for environmental analysis. The method was applied to influents and effluents of sewage treatment plants in Japan, with target chemicals identified using retention times, exact precursor and product ions and their ion ratios that are obtained by Swath. Matrix effects that might affect quantification were examined using extracts of influent (100 x concentrated) and effluent (400 x concentrated) and methanol spiked with 213 pesticides (100 ng each). Average ratios of detected amounts between the extracts and the methanol solution were 89.8 (influent) and 91.7% (effluent) with RSDs of 22.6 and 22.6%, respectively, showing that matrix did not affect quantification. The number of substances detected in an influent and an effluent collected in autumn 2017 in Kitakyushu City were 74 and 86, respectively. The detected compounds were mainly PPCPs, but 8 and 16 pesticides were also detected. Total concentrations were 95.6 and 35.8 ug/L, respectively; the removal ratio was 62.9 %. Emission loads of the targets from human activities were 44.5g/1000 capita/d. The data confirmed that this newly developed method is very useful because of the large number of targets, reliable identification and quantification performance. In addition, since the method measures samples by scan, non-target analysis and retrospective analysis can be done using exact mass spectra.

### 329 Pharmaceutical concentrations in Great Lakes tributaries: Chemical and site prioritization based on the ToxCast High Throughput Screening database

S.R. Corsi, *US Geological Survey / Upper Midwest Water Science Center; L.A. DeCicco, US Geological Survey / Office of Water Information; M. Lutz, US Geological Survey / Water Resources Division; P. Lenaker, US Geological Survey / Wisconsin Water Science Center; E.T. Furlong, M.C. Noriega, US Geological Survey / National Water Quality Laboratory; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory; B.R. Blackwell, G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; S. Oliver, US Geological Survey / Wisconsin Water Science Center*

Great Lakes tributary monitoring results during the first six years (2010-2015) of the Great Lakes Restoration Initiative indicated that the level of pharmaceutical chemical contamination in streams have the potential to exert adverse impacts on aquatic life. Subsequently, a more in-depth study was undertaken to examine potential biological effects of pharmaceuticals on fish and wildlife in tributaries of the Great Lakes. Samples from 45 tributary locations were analyzed for pharmaceuticals from an established pharmaceutical method (109 compounds) and preliminary results from a method under development (more than 180 additional compounds under consideration). Samples were collected during 2017 and 2018 to examine variability in pharmaceutical prevalence due to land use, hydrology, and season throughout the Great Lakes region. Sampling locations included very small (< 20 $km^2$) to very large (6330 $km^2$) watersheds with a full range of urban land cover (0-100%) and variable wastewater effluent influence (0-28% of mean annual flow). Relevance of pharmaceutical exposure to aquatic life is being evaluated by comparison to traditional water quality benchmarks and the USGS Health-Based Screening Levels for pharmaceuticals, as well as results from "high throughput" in-vitro biological assay results from the USEPA ToxCast program. Collectively, these sources include available information for about 2/3 of the 289+ pharmaceutical compounds monitored. Results will be used for screening and prioritization of chemicals and sites with the greatest potential for adverse biological impact using Exposure—activity ratios with ToxCast endpoints and toxicity quotients with other benchmarks through the R-package, toxEval. These analyses are being used as part of the Great Lakes Restoration Initiative to focus current and future investigations that will help understand likely adverse outcome pathways in organisms, and to formulate possible remediation strategies. The contents of this abstract neither constitute, nor necessarily reflect, official USEPA policy.

### 330 Effect-based approach for evaluation of brominated dioxins and dioxin-like compounds in effluents and indoor air from BFRs treating facility

G. Suzuki, *C. Michinaka, H. Matsukami, National Institute for Environmental Studies / Center for Material Cycles and Waste Management Research; S. Hashimoto, National Institute for Environmental Studies / Center for Environmental Measurement and Analysis; S. Sakai, Kyoto University / Environment Preservation Research Center*

Brominated dioxins, particularly polybrominated dibenzo-*p*-dioxins and dibenzofurans (PBDD/Fs), have been found in various samples from brominated flame retardants (BFRs) treating facilities related to fire-proof materials and electronics in the developed and developing countries. PBDD/Fs are dioxin-like compounds based on criteria of WHO/UNEP expert meeting. Because of that, WHO toxic equivalents (TEQs) should be also determined for PBDD/Fs as well as chlorinated dioxins. On the other hand, some kinds of BFRs currently used may also be dioxin-like compounds according to our unpublished data. Therefore there is a need for effect-based approach by using cell-based assay in combination with instrumental analysis to properly evaluate dioxin-like compounds related to BFRs for their risk management. In this study, in order to aim for an efficient and effective risk management for those compounds, we improved the effect-based method we previously developed for the detection of brominated dioxins, applied this to effluents and indoor air of several facilities related to BFRs in Japan, and considered how to utilize this method in the further investigation. The improved method was resource-saving and time-saving method with high reproducibility and high recovery rate, estimating 2,3,7,8-TCDD-equivalent (TCDD-EQ) of brominated dioxins by using cell-based assay and cleanup/separation technique. And then, both the TCDD-EQ of brominated dioxins fraction ($TCDD\text{-}EQ_{Br\text{-}DXN}$) and the brominated dioxins-derived WHO-TEQ ($WHO\text{-}TEQ_{PBDD/Fs}$) for effluents ($n$=20) and indoor air ($n$=20) were obtained by using the improved method and the GC-HRMS analysis with the WHO toxicity equivalency factor (TEF), respectively. The ratios of the $TCDD\text{-}EQ_{Br\text{-}DXN}$ to the $WHO\text{-}TEQ_{PBDD/Fs}$ was at least 0.1 or more, suggesting that action values should be 10% of their standard limits based on $WHO\text{-}TEQ_{PBDD/Fs}$ when the improved method used as a tool for screening. This means we must steps to analyze PBDD/Fs concentration by using GC-HRMS when action values are exceeded. Furthermore, several samples clearly indicated that ratios were more than 10, suggesting that unidentified brominated dioxin-like compounds may have contributed to the $TCDD\text{-}EQ_{Br\text{-}DXN}$, as mentioned earlier. In conclusion, the method improved here would be useful for an efficient and effective risk management of dioxin-like compounds resulting from the lifecycle of consumer product containing BFRs.

### 331 Removal of Emerging Organic Contaminants in an Engineered Hyporheic Zone using High Resolution Mass Spectrometry

*K. Peter, University of Washington Tacoma / Center for Urban Waters; S. Herzog, University of Indiana Bloomington / School of Public and Environmental Affairs; Z. Tian, C. Wu, University of Washington Tacoma / Center for Urban Waters; J. McCray, Colorado School of Mines / Civil and Environmental Engineering; K. Lynch, Seattle Public Utilities; E.P. Kolodziej, University of Washington, Tacoma/Seattle / Center for Urban Waters Interdisciplinary Arts and Sciences Civil and Environmental Engineering*

The hyporheic zone (HZ), the interface of surface water and groundwater exchange in a lotic system, is a natural bioreactor that can attenuate chemical contaminants. Given this attenuation capability, including hyporheic design elements (HDEs) in urban stream restoration projects can provide simultaneous biological health, habitat, water quantity, and water quality improvements. Engineered hyporheic zones can provide the potential to treat non-point source pollution (i.e., urban stormwater) via in-stream treatment, saving space and improving water quality. Here, we characterized the hydrology and water treatment potential of an engineered hyporheic zone in the Thornton Creek Watershed in Seattle, WA during both baseflow and stormflow conditions. Dye and bromide were used to hydraulically link downwelling and upwelling zones and estimate flow path hydraulic retention times (HRTs) to guide water quality sampling. We applied non-target and suspect screening analysis via high resolution mass spectrometry (HRMS) to detect and identify novel emerging contaminants, then evaluated water quality improvements during HZ transport. After data reduction, we prioritized HRMS features for identification using suspect screening and peak area (abundance) filters. We identified ~70 contaminants with confidence level S2b or higher, including 6 families of poly(ethylene glycols), poly(propylene glycols), and ethoxylates. Expanding on previous data analysis strategies, we evaluated the fate of both identified contaminants and non-target features in the HZ, observing an overall water quality improvement in hyporheic flow relative to surface flow. During stormflow, 56-77% of non-target detections were degraded or eliminated via hyporheic flow, with higher contaminant removal efficiencies at longer hydraulic retention times.

### 332 Bisphenols in San Francisco Bay Water

*I. Shimabuku, San Francisco Estuary Institute; Y. Wu, Indiana University, Bloomington / Cooperative Wildlife Research Laboratory and Department of Zoology; D. Chen, Jinan University / School of Environment; J. Sun, R. Sutton, San Francisco Estuary Institute*

Bisphenols are synthetic, organic compounds with broad uses including the manufacture of polycarbonate plastics, epoxy resins that line food containers and water pipes, and as a coating on thermal paper, among others. High production volumes have led to the ubiquitous presence of Bisphenol A (BPA), the most commonly produced bisphenol, in the environment. Bisphenol A is an endocrine disruptor and is highly toxic to aquatic life, with a predicted no effect concentration (PNEC) of less than 1 μg/L. Human health concerns have led to bans and phase-outs of some uses of BPA, which in some cases has resulted in increased use of structurally-similar substitutes that are not well-understood with regards to both their toxicity and their presence in the environment. Serving as home to over seven million inhabitants and a breadth of industry, the San Francisco Bay is an excellent location to screen for the presence of bisphenols in the environment. Sixteen bisphenols were measured in ambient water samples collected from 22 Bay sites in 2017. Findings from this study will be presented to support a more robust understanding of the various bisphenol compounds present in waterbodies near urban centers.

### 333 Prioritizing Contaminants in Complex Mixtures using In vitro-based Metabolomics and Multivariate Statistics

*T. Collette, D. Ekman, USEPA / National Exposure Research Laboratory; P.M. Bradley, US Geological Survey / South Atlantic Water Science Center; Q. Teng, USEPA / National Exposure Research Laboratory*

Chemicals occur as complex mixtures in developed watershed streams, and the makeup of these mixtures can differ dramatically based on land use and a variety of other factors. While it is accepted that some chemicals (and chemical mixtures) are detrimental to ecosystem health, there is rarely compelling evidence as to which chemicals, chemical classes, or defined mixtures are the most biologically impactful. To address some of these needs, the USGS and the EPA partnered to conduct an extensive field study of 38 streams across the US during 2012-2014. Water was collected for expanded target analysis (916 total analytes), and split samples were submitted to a variety of effects-based tools for evaluating the biological impacts of chemicals (and other stressors) in these waters. Here, we discuss an untargeted NMR-based metabolomic assessment of these samples, using cultured zebrafish liver cells (ZFL). One goal was to use partial least squares (PLS) regression to determine which stressors most strongly co-varied with changes in metabolite profiles, and conversely, which stressors showed little to no covariance and thus potentially less biological relevance. Of 455 stressors submitted to PLS regression (including 406 anthropogenic organic chemicals detected in at least one site, 37 inorganics, and 12 water quality parameters), 280 displayed significant covariance with impacts on the ZFL metabolome. To provide a coarse ranking, these 280 stressors were sorted into quartiles according to the strength of their covariance. The top (i.e., strongest covariance) quartile comprised a mix of legacy contaminants (e.g., PCBs), contaminants of emerging concern (CECs), and a few inorganics. Also, several non-chemical stressors (e.g., pH) displayed strong covariance, highlighting the ability of this untargeted approach to capture impacts from these types of stressors as well. Interestingly, none of the 10 most frequently detected organics (common pesticides and pharmaceuticals) occurred in the top quartile, and 6 of the 10 were omitted altogether due to minimal covariance. The 10 organics that were detected at the highest median concentration were better represented in the top quartile; however, overall, there was no correlation between occurrence level and ranking within the PLS model. These and other aspects of this work will be presented to showcase the utility of multivariate statistics and in vitro-based metabolomics for prioritizing contaminants in complex mixtures.

### 334 Using predicted estrogenicity to drive High Resolution LCMS non-target chemical identifications in complex environmental samples

*G. Black, University of California, Davis / Agricultural & Environmental Chemistry*

The persistence of consumer product chemicals has been observed in solid and aqueous wastewater treatment plant discharges worldwide. A number of these chemicals has been shown to cause endocrine disruption, for example in organisms downstream from wastewater discharge locations. Sewage sludge is a concentrated, complex mixture of compounds that may ultimately be introduced into the environment via land application practices. Looking for consumer products chemicals, and their transformation products, in sewage sludge offers a bottom-up approach to look for compounds that have persisted beyond their intended period of use and the robust treatment processes employed at wastewater treatment plants. Fourteen wastewater treatment plants in California have contributed end-of-treatment sludge samples for this study. In coupling High Resolution LC-QTOF-ESI-MS non-target screening with predicted estrogenicity data using the VEGA toxicity prediction model, we are able to prioritize chemical identifications of biologically relevant, persistent organic pollutants. Furthermore, in-vitro bioassay data and effects-directed analysis will be used to further analyze the estrogenicity of this complex matrix and attempt to account for cumulative estrogenicity through non-target chemical identifications.

## A Dialogue and Debate on Science, Sustainability and the Science of Sustainability

**336 Cross fertilization between eco-innovation and life cycle assessment: A pathway to circular economy**

W.H. Motta, *IBICT / Information Science Post-Graduation Program*

Since the industrial revolution, the use of natural resources and the generation of waste has grown in an accelerated and uncontrolled way, in a process that has led to the so-called ecological crisis. This reality, derived directly from the current economic patterns of exacerbated production and consumption, characterized by the logic of "extract-production-consumption-disposal", which assumes that resources are plentiful, available, and cheap. The circular economy proposal arises as an alternative to this traditional linear approach, proposing a model based on "reuse-repair-renew-recycle" existing materials and products, in order to tackle this serious ecological crisis. Circular economy ideals then proposes that resources are kept in use for as long as possible, thus proposing that inputs and products need to be managed in a more eco-efficient way throughout their entire life cycle. Because of its characteristics, life cycle assessment (LCA) has the potential to play an important role in this paradigm shift not only because of its already recognized potential for evaluating the environmental impacts associated with all the stages of the life cycle of a product but also because of its still little discussed role as a promoter of opportunities and possibilities to eco-innovate. In this sense, for the transition to the circular economy, life cycle approach has shown to be an appropriate and comprehensive tool to support decision-making processes related to environmental issues in business and also for their important characteristic of providing perspectives for eco-innovation. The present work aims, through a review of the recent literature, to analyse the ways for a conceptual approximation of the approaches of these three axes of knowledge: circular economy, eco-innovation and LCA. The discussion takes into consideration and aims to shed light on the cross fertilization between eco-innovation and LCA as well as consider the individual participations of both areas of knowledge, seeking to evidence their potential to contribute to the necessary transition to the circular economy. This review and a logical analysis of the three approaches highlight specific points where the approach is recognized not only as feasible but also advantageous, leading to the conclusion that the path of integrating approaches is promising.

**337 The Science of Sustainability? Scaling the interaction between Resilience and Robustness**

B. Dyson, *T. Canfield, J.F. Carriger, Jr., USEPA / National Risk Management Research Laboratory*

The failure of social-ecological systems to be robust to changing conditions points to a need to better understand ecosystem response and ecological resilience as a guide to ensure sustainability of ecosystem service provision. While a systems-level understanding of resilience may be useful, and potentially necessary, it is not sufficient for defining sustainability requirements e.g. the four questions: what; for whom; how long; at what cost, and relevant decision metrics e.g. Triple Bottom Line, that are needed for localized provision of sustained services. Sustainability of social-ecological systems is a function of the interaction between a larger dynamical system understanding of ecological resilience and more localized decision-making and designing of robust systems for maximizing the sustainability of ecosystem service delivery. Understanding ecosystem resilience characteristics provides a larger context or set of operating principles for incorporating adaptability into the planning and execution of service delivery system. Examples include hybrid approaches such as green infrastructure and decentralized networks for water treatment and waste management. Modeling (system dynamics) and analytical approaches (decision analysis/MCDA) for system characterization, problem formulation, option development and implementation will be discussed.

**338 On the integration of complexity and integrity to restore and sustain the Blackfoot Watershed, Montana**

C. Curtin, *Blackfoot Challenge*

For more than 25 years Montana's place-based collaborative the Blackfoot Challenge has focused on sustaining the cultural and ecological integrity of the Blackfoot River watershed in a 1.7 million portion of the headwaters of the Columbia River. Famed for its depiction in the book and movie "A River Runs Through It" two decades ago the river was severely polluted, many of the key wildlife species were missing from the valley, and wooded uplands were too frequently degraded by logging. Today the watershed is considered one of the healthiest in the US. Top carnivores such as grizzly bear and wolf have returned. We have an overall species diversity comparable to the world renowned Yellowstone National Park, despite seven towns and over 8,000 people being located in the watershed. Much of this success can be attributed to a process that recognizes that managing complexity requires designing for complexity in an open and transparent process. The governance is largely focused on building and sustaining trust and it is an excellent example of how systems science needs to blend social and ecological perspectives through principled approaches. The governance and collaborative stewardship process is a significant example of how getting the science right requires building durable institutions and that in restoring large systems almost everything flows from maintaining and sustaining the social capital that allows collaboratives to "Get Stuff Done." In this talk I use the Blackfoot Challenge example to illustrate how science, conservation, restoration, and culture are entwined and how institutional design is crucial to maintaining large and complex systems. I also focus on how climate, fire, wildlife, and rural economies interact to influence the watershed and how we are redesigning and realigning programs to meet existing realities though a complex systems-based approach.

**339 Four Sustainability Questions and Seven Things**

C. Stahl, *USEPA Region III*

An analysis or discussion of a set of indicators that include some economics, some societal and some environmental factors (i.e., the Triple Bottom Line: Economics, Society and the Environment) are many times considered an adequate addressing of sustainability. The fallacy in this approach is that without the Environment, neither Economy nor Society could exist. When problem formulation about sustainability does not accurately reflect the problem to be addressed, we often solve the wrong problem or exacerbate the problem. Sustainability is a wicked problem (Rittel and Webber, 1973). Therefore, it is important to be explicit and deliberate about how we conduct problem formulation for sustainability. An alternative to this is the concept of the Four Sustainability Questions posed by Allen, Tainter and Hoekstra (2003) in "Supply-side Sustainability." These Four Questions are: 1) What do we want to sustain?, 2) For Whom do we want to sustain it?, 3) For How Long do we want to sustain it?, and 4) At What Cost are we willing to sustain it? Juxtaposed against Patel and Moore's recent book, "A History of the World in Seven Cheap Things," this talk sets the stage for thinking about and acting on sustainability in a fundamentally different way than simply ensuring that the discussion include indicators for economics, society and the environment.

**340 Application of sustainabilty as a value in hard rock mining**

E.J. Dorward-King, *Newmont Mining Corporation / Sustainability and External Relations*

The understanding of and definition of sustainable development or sustainability has evolved over the past decades. This presentation will consider that evolution in the context of the global large scale mining industry and will describe the current application of sustainability by Newmont Mining, where sustainabilty is viewed as a value rather than as a technical imperative with engineering solutions. While application of technical solutions based on scientific data and engineering will be discussed, also included will be the social and economic considerations on which decisions, programs and actions are based. Specific case studies from Australia, Ghana and the USA will be discussed, including approaches and data for economic impact assessments, local economic development, biodiversity and habitat restoration, watershed stewardship, and mine closure planning and implementation. The concept of the triple bottom line as a foundational model for sustainability will be defended.

**341 She Blinded Me With Science ... And Bored Me With Math ... Until I Understood Systems!**

*R. McCormick, Bureau of Land Management*

Yes, it’s sad the polar bears don’t have ice to hunt on, but do the societal math. 9+ billion humans, fixed land base, finite fossil fuel reserves, very low energy ROI for most alternatives to fossil fuels, clear SLR regardless of who or what you want to point the finger at ... these affect every sector of SETAC, every GU, peoples in Europe, native villagers on the Chukchi Sea in Alaska, and Islanders in the Pacific. The math of sustainability and resilience is inexorable, and won’t wait for SETAC members to recognize it. If we were to re-imagine the “Scope of the Meeting” statement on the SETAC website to reflect current sustainability science, it might look like this: The essence of sustainability in practice is to act with increased resilience in mind, and in all aspect of living, working and playing on a social – ecological landscape. The thrust of this meeting is to re-align the importance of sustainable economic development within the lens of ecological and societal stewardship. In this context, stewardship represents the practice of resilience thinking and action towards maintaining and growing a sustainable society. One of the biggest challenges facing society in this endeavor is identifying ways to decouple the historical connection between economic growth and ecological integrity, and the resultant societal effects. To solve this wicked problem, SETAC advocates for evaluating sustainability as a single pillar with economic systems embedded in the societies they emerge from, and in turn the ecological systems in which both reside. This meeting offers opportunities to feature the connections between desired ecosystem goods and services, stable flourishing societies, and sustainable economies. Others in this session will define the single-pillar concept of sustainability. The single-pillar perspective places economies within societies, which in turn are embedded within and wholly dependent on the flow of ecosystem services to the society. If the capacity of the ecological system to provide desired ecosystem services declines, the society must adjust accordingly or experience disruptive societal turbulence. Coping with the ebb and flow of ecosystem services is the key to any society and to its economic status. Discourse in the early days of the 21st Century is disjointed, disagreeable, and dangerous. Holistic, system-based approaches are the only way to overcome this, and science is the process we will use.

## Human Exposure to Emerging Environmental Contaminants

**342 Concentrations of Perfluoroalkyl Substances in Drinking Water, Indoor Air and Dust in Ireland: Implications for Human Exposure**

*D. Drage, The University of Birmingham / School of Geography Earth and Environmental Sciences; S.J. Harrad, The University of Birmingham; M.A. Abdallah, University of Birmingham / Division of Environmental Health and Risk Management / College of Life and Environmental Sciences; N. Wemken, M. Coggins, National University of Ireland Galway*

This study assesses for the first time, exposure of the Irish population to perfluoroalkyl substances (PFAS) in common indoor microenvironments and drinking water. To do so, passive air sampler (PAS) and floor dust samples were collected from Irish homes, cars, offices and primary school classrooms (n=30 per microenvironment) between August 2016 and January 2017. PAS consisting of a sorbent (XAD-3) impregnated polyurethane foam disk (PUF) were deployed for 60 days, placed on elevated surfaces in homes, offices, and schools, and the floor behind the passenger or driver’s seat in cars. Dust samples were collected by vacuuming floors following methods previously described. In addition, 60 tap water samples were collected from the same homes and offices, with a further two samples of each of five major mineral water brands (i.e. 10 bottled water samples in total). PFAS were detected in all air and dust samples with an average ΣPFAS concentration of 290 pg/m$^3$ (range: 0.03 –2300 pg/m$^3$) and 67 ng/g (range: 0.4 – 4000 ng/g) respectively. In air, PFOA (average: 140 pg/m$^3$, range: < 0.1 – 1200 pg/m$^3$) was the dominant congener in 60% of samples. This was followed by PFBS (average: 38 pg/m$^3$, range: < 0.2 – 310 pg/m$^3$) and PFOS (average: 73 pg/m$^3$, range: < 0.2 – 1600 pg/m$^3$) that were dominant in 21% and 18% respectively. In dust, PFBS (average 16 ng/g, range < 0.1 – 170 ng/g) was the dominant PFAS in 68% of samples. PFOS (average: 27 ng/g, range: < 0.1 – 2700 ng/g) was dominant in 15% of samples, and PFOA (average: 8.1 ng/g, range: < 0.05 – 380 ng/g) was dominant in 8% of samples. PFAS were detected in all bottled water samples and in 86% of tap water samples. The average ΣPFAS concentration in bottled water samples was 16 ng/L (range: 0.17 – 64 ng/L). The average ΣPFAS concentration in tap water was considerably lower at 0.94 ng/L (range: < 0.5 – 16 ng/L). PFBS was the dominant congener in bottled water making up 75% of the average ΣPFAS content followed by PFOS (12%). PFBS was less dominant in tap water (51%) with PFOA making up 30% of ΣPFAS. Our data are consistent with a shift towards the use of lower carbon chain PFAS.

**343 Identifying chemicals in the indoor environment that can serve as tracers for estimating children’s non-dietary ingestion from dust exposure**

*D. Panagopoulos, ORISE at USEPA / Department of Indoor Environment; J.R. Sobus, E.M. Ulrich, USEPA / Office of Research and Development / National Exposure Research Laboratory; T.M. Young, University of California, Davis / Civil and Environmental Engineering; N.S. Tulve, USEPA / Office of Research and Development / National Exposure Research Laboratory*

Children are exposed to dust in indoor environments through their regular activities. Dust is known to be a sink for many chemicals from indoor sources such as building materials, furniture, cleaning agents, insecticides and personal care products. Partitioning and accumulation of chemicals in dust contribute to children’s uptake of these chemicals through non-dietary ingestion, inhalation and dermal contact. Dust is routinely collected in observational human exposure studies but its potential to be used as a standard metric for human exposure to chemicals remains unclear due to the large variability in dust composition and human exposure patterns. Previous studies have tried to calculate dust ingestion rates using metals or other earth elements as tracers. These approaches have significant limitations since the proposed tracers are present in matrices besides dust. Our study aims to identify organic chemicals that are unique and ubiquitous in dust, and that can be used as tracers to calculate dust ingestion rates for children. We collected data from three studies that sampled: 1) 50 homes across the U.S., 2) 38 homes in CA and 3) one house in NC with samples collected from each room and at three time-points. Using non-targeted analysis methods, we generated data on thousands of observed dust features, and tentatively identified compounds that were ubiquitous in each sample set (i.e., appearing across homes, rooms, and time points with high detection frequency [DF]). Candidate compounds include tris-(2-chloroisopropyl)phosphate (plastic production, 98% DF); 2-hydroxy-4-methoxybenzophenone (plastic UV stabilizer, 90% DF); fipronil (insecticide, 95% DF) and piperine (black peppercorn, 85% DF), among others. The detected compounds covered a large spectrum of physicochemical properties, from nonpolar and semivolatile to polar and non-volatile compounds. Future work will include applications of statistical and environmental fate modeling to track emission sources and describe the partitioning of the detected chemicals in the indoor environment to better understand their utility as tracers. More details on the candidate compounds and supporting information will be presented.

**344 Targeted and non-targeted analysis of serum exposome using two-dimensional gas chromatography coupled to high resolution mass spectrometry**

*K.J. Jobst, Ontario Ministry of Environment and Climate Change; A. Mell, McMaster University; R. Di Lorenzo, Hospital for Sick Children; E. Reiner, Ontario Ministry of the Environment and Climate Change / Chemistry; J.G. Sled, Hospital for Sick Children; K.J. Rosnack, Waters Corporation / Food and Environmental Global Markets*

Environmental risk factors, such as diet, smoking and exposure to environmental toxicants, may contribute more than genetic factors to the risks of cancer and other non-communicable diseases. Persistent organic pollutants (POPs) represent an important subset of toxicants that exhibit common characteristics, such as persistence, toxicity and a tendency to bioaccumulate. This contribution reports on a sensitive, quantitative and high-throughput method for the analysis of legacy and emerging halogenated POPs in 200 µL of serum. Serum samples were collected from mothers (n=68) at Mount Sinai Hospital (Toronto). The method employs stir-bar sorptive extraction, which enables preparation of >20 samples in four hours. Detection is achieved using thermal desorption gas chromatography coupled to a quadrupole time-of-flight mass spectrometer. Sensitivity is enhanced by atmospheric pressure gas chromatography, a soft ionization technique that maximizes the yield of molecular ions. A Zoex ZX2 modulator enabled GCxGC separation, which significantly increased the number of detectable chemical features. Data processing and visualization was performed using GCImage HRMS version 2.5. Unknown halogenated compounds were identified using custom macros. The identities of most environmental toxicants and their roles in causing chronic diseases are not known. The full scan data acquired using the qTOF represents a trove of data that can be retrospectively searched for as yet unidentified toxicants. The results of this study indicate that identification of trace level POPs is feasible provided a strategy is implemented to effectively remove interfering chemical features. To accomplish this: (1) a library of chemical features was generated through GCxGC-HRMS analysis of pooled samples obtained from study participants. GCxGC separation proved crucial to obtain clean mass spectra that would otherwise be obscured by matrix; (2) a software filter was devised to separate halogenated from non-halogenated compounds on the basis of accurate mass and isotope ratio measurements; (3) the filter was applied to the pooled samples, generating a suspect list of features which was used to interrogate the samples obtained from individual participants. Preliminary results indicate the presence of multiple classes of POPs that show an inversely proportional correlation to birth weight. These POPs include a number of halogenated chemicals whose identities have not yet been reported.

**345 Urinary concentrations of chlorophenols in pregnant women and children from Sheyang Birth Cohort**

*C. Wu, Fudan University; C. Wu, California Department of Public Health; J. Guo, Fudan University / School of Pubilc Health; D. Lu, Shanghai Municipal Center for Disease Control and Prevention; J. She, Environmental Health Lab / CA Department of Public Health; Z. Zhou, Fudan University*

Chlorophenols (CPs), have been widely applied as raw materials or intermediates for fungicides, insecticides, and wood preservatives for several decades. Epidemiological studies indicated long-term exposure to low level of CPs were associated with potential adverse effects of human health. However, reports of current exposure levels to these chemicals in pregnant women and children are very limited. In this study, a total of 1,100 mothers were included in the Birth Corhort Study from Sheyang County, Jiangsu Province, and 436 3-year-old children were followed up. Questionnaire surveys were conducted to pregnant women and their children considering general information, disease history, lifestyle characteristics and living environment. Five CP compounds, namely, 2,4- dichlorophenol (2,4-DCP), 2,5- dichlorophenol (2,5-DCP), 2,4,5-trichlorophenol (2,4,5-TCP), 2,4,6-trichlorophenol( 2,4,6-TCP) and pentachlorophenol (PCP), were measured in urine by gas chromatography-tandem mass spectrometry (GC-MS-MS). The geometric mean values of urinary 2,4-DCP, 2,5-DCP, 2,4,5-TCP, 2,4,6-TCP and PCP concentrations of pregnant women were 0.80 µg/L, 2.34 µg/L, < LOD, 1.23 µg/L and 0.28 µg/L, respectively. CPs were widely presented in all maternal urine during pregnancy except 2,4,5-TCP with detection rate of 29.6%. Five CPs were correlated each other using Pearson correlation analysis. Multiple linear regression indicated urinary 2,5-DCP concentrations were significantly associated with maternal age during pregnancy ($p< 0.05$). CPs exposure were also significantly associated with sampling seasons ($p< 0.05$). Additionally, geometric mean values of children urinary 2,4-DCP, 2,5-DCP, 2,4,5-TCP, 2,4,6-TCP and PCP concentrations were 2.48 µg/L, 4.28 µg/L, 0.02 µg/L,1.21 µg/L and 0.08 µg/L, respectively. CPs can be widely detected in children urine samples except for 2,4,5-TCP with a detection rate of 53.3%. Pearson correlation analysis indicated urinary 2,4,6-TCP concentrations were related to DCPs and PCP ($p< 0.05$). Significant correlations between maternal CPs exposure and children CPs exposure were not observed. These findings suggested that both pregnant women and their children in study region were widely exposed to five CPs.

**346 Elevated Concentrations of Bisphenols, Benzophenones, and Antimicrobials in Pantyhose Collected from Six Countries**

*J. Li, Wadsworth Center, New York State Department of Health; K. Kannan, Wadsworth Center, New York State Department of Health / Division of Environmental Health Sciences*

Pantyhose is a skin-tight clothing made of synthetic fibers and worn by women in many countries. During the production of fabrics from synthetic fibers, many chemicals are used to enhance the performance and those chemicals can pose a risk of exposure to consumers. Little is known regarding the occurrence of and dermal exposure to chemicals present in pantyhose. In this study, concentrations and profiles of 23 endocrine disrupting chemicals including bisphenols, benzophenones, chlorophenols, parabens, and triclocarban (TCC) were determined in 74 pantyhose samples collected from six countries. Pantyhose samples were analyzed by two extraction methods, one by complete dissolution of the fabric and another by traditional ultrasonic extraction. Dissolution of the fabric in 1,1,1,3,3,3-hexafluoro-2-propanol/chloroform yielded up to 286 times higher concentrations of several target chemicals than the ultrasonic extraction. Bisphenol S (BPS) and bisphenol A (BPA) were found in 100% and 96% of the samples at median concentrations of 1430 and 14.3 ng/g, respectively. Several brands of pantyhose contained BPS, bisphenol F (BPF), benzophenone-1 (BP-1), ethyl-paraben (EtP) and TCC at milligram per gram concentrations. Benzophenone-3 (BP-3), 4-hydroxy benzoic acid (4-HB), methyl- (MeP), and propyl-parabens (PrP) were found in ≥ 85% of the samples, at median concentrations on the order of several tens to hundreds of nanograms per gram fabric. Black pantyhose made in Japan and China with 21-50% Spandex contained the highest concentrations of BPS (2.2 mg/g), BP-1 (2.4 mg/g) and EtP (88 µg/g). Calculated dermal exposure doses to BPS, BP-1 and EtP by women via pantyhose were as high as 45900, 50600 and 1800 pg/kg-bw/day, respectively. Pantyhose is a source of exposure of women to several endocrine disrupting chemicals.

**347 A pilot study in occupational exposure to phthalates and organophosphorus esters among Canadian nail technicians**

*L.V. Nguyen, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; V. Arrandale, S. Kalenge, Cancer Care Ontario / Occupational Cancer Research Centre; T. Kirkham, University of Toronto; L. Holness, St. Michaels Hospital; M.L. Diamond, University of Toronto / Department of Earth Sciences*

Phthalates and organophosphorus esters (OPEs) are endocrine disrupting chemicals associated with adverse health outcomes such as reproductive disorders and neurodevelopmental toxicity. Nail technicians are potentially exposed to elevated levels of phthalates and OPEs as they are present in personal care products (PCPs) including nail polish and nail removers. Two previous studies have estimated phthalate exposures in nail salons by using stationary levels. However, no studies have measured personal exposure to phthalate and OPEs in nail salons to date. In this pilot study, we report on concentrations and profiles of selected phthalates and OPEs in air at nail salons in Southern Ontario, Canada. Two stationary and three personal air samples were taken during two 8-hour workdays in two nail salons. Air samples were collected using OSHA versatile samplers (PUF/XAD-2/PUF sandwich) with personal SKC pumps at 2 L/min and analysed for eight phthalates and four OPEs by gas chromatography with mass spectrometry (GC-MS). OPEs had the highest concentrations among all compounds measured. All OPEs and half of the phthalates, except BzBP, DnOP, DiNP and DiDP, had detection frequencies of 100%. The concentration profile of these compounds was TCIPP > TPhP > TCEP > TDCIPP > DEHP > DEP > DiBP > DnBP. Levels of target compounds found in personal air samples were 1-4 orders of magnitude higher than those found in stationary air samples. The median concentrations of TCIPP in personal samples were 816 ng/$m^3$. The most abundant phthalate was DEHP with a range of concentrations from 1.3 to 243 ng/$m^3$. Total air concentrations of DEP, DiBP, DnBP, BzBP and DEHP found in stationary samples were four orders of magnitude lower than those reported from US hair and nail salons (Tran et al., 2015) and Vietnamese hair salons (Tran et al., 2018). However, levels of OPEs reported here were around three orders of magnitude higher than those values found in Canadian homes (Yang et al., 2018). In conclusion, this pilot data indicates that nail technicians in Ontario studied here, experience inhalation exposure to phthalates at low levels and OPEs at elevated levels.

**348 Examining Children's Exposure to Organophosphate Esters Using Silicone Wristbands**

*S. Hammel, A.L. Phillips, K. Hoffman, A.M. Lorenzo, A. Chen, Duke University / Nicholas School of the Environment; T.F. Webster, Boston University School of Public Health / Dept Environmental Health; H.M. Stapleton, Duke University / Nicholas School of the Environment*

Organophosphate esters (OPEs) are commonly used as flame retardants and plasticizers and are frequently detected in indoor environments. Human exposure to these compounds is widespread, and OPE urinary metabolites are ubiquitously detected in the population. This is of concern for children who often experience higher exposures and are vulnerable to adverse long-term health effects. Recently, silicone wristbands have been used as personal passive samplers to examine exposures to semi-volatile organic compounds (SVOCs). Among adults, OPEs were significantly associated with metabolites from pooled urine samples ($r_s$=0.4-0.7; $p<$ 0.05). Here, we examine the utility of wristbands for assessing children's exposure to 21 OPEs through comparisons to pooled urinary metabolites, house dust, and hand wipes. Children ages 3-6 years and their families were recruited in 2014-16 to participate in a study examining SVOC exposures. Paired hand wipes and dust were collected in the home, and children wore pre-cleaned wristbands (n=74) and provided 3 urine samples (collected over a 48-h period and pooled) in support of the study. All measured OPEs were frequently detected on >85% of bands, which suggests children's exposure is common. Geometric means ranged from 6.1 to 614.8 ng/g band, with triphenyl phosphate (TPHP) having the highest concentration overall. OPEs on the wristbands were positively associated with metabolites from pooled urine samples. In particular, tris(1,3-dichloroisopropyl)phosphate (TDCIPP) on the wristbands was significantly correlated with its corresponding urinary metabolite ($r_s$=0.51, $p<$ 0.01). Isopropylated triarylphosphate esters (ITPs) were also significantly correlated with their metabolite, isopropylphenyl phenyl phosphate (ip-PPP; $r_s$=0.24-0.38; $p<$ 0.05). Average outdoor temperature was positively and significantly associated with TDCIPP on the wristbands ($10^B$=1.05), which reflects a similar trend observed for the urinary metabolite; however, this association was not observed for hand wipes. The magnitude of correlation between OPEs in exposure matrices and paired urinary metabolites for wristbands was roughly equivalent to hand wipes in a few cases and were consistently greater than house dust. These results suggest that wristbands and hand wipes provide an improved measure of individual exposure to OPEs compared to house dust. Due to the ease of sample collection, they hold potential to support large-scale biomonitoring and epidemiological studies.

**349 Investigating human exposures to flame retardants and polycyclic aromatic hydrocarbons using silicone wristbands**

*S. Wang, K. Romanak, A. Salamova, W. Stubbings, Indiana University, Bloomington / School of Public and Environmental Affairs; M. Hendryx, Indiana University / School of Public Health; V.H. Arrandale, Cancer Care Ontario & University of Toronto / Occupational Cancer Research Center; M.L. Diamond, University of Toronto / Department of Earth Sciences; M. Venier, Indiana University / SPEA*

Human exposure to organic chemicals remains crucial for informing public health. Compared to active samplers, personal passive samplers, have the capacity to represent exposures integrated over a longer time-period, are cost-effective and less-invasive. Although silicone wristbands have recently been used for characterizing personal exposure to a variety of chemicals, information on the exposure represented by a wristband is still limited. We hypothesized that wristbands integrate inhalation and dermal exposure. Wristbands, active and passive personal air samplers, and hand wipes were used to examine the relationship between routes of exposures. Each adult participant (n=10) wore one silicone wristband, one silicone brooch/badge (PDMS) and an OVS active personal air sampler containing a glass fiber filter followed by a PUF/XAD/PUF sandwich for 72 consecutive hours. Hand wipe samples were also collected each time before washing hands during the 72 hour period. Samples were extracted and analysed for 9 polycyclic aromatic hydrocarbons (PAHs) and 13 flame retardants (FRs), including novel brominated flame retardants (NBFRs), polybrominated diphenyl ethers (PBDEs), and organophosphate esters (OPEs) using gas chromatographic mass spectrometry (GC-MS). In most samples, congeners BDE-47, -99 and -209 were the most abundant among PBDEs, EHTBB and DBDPE among NBFRs, TCEP, TCIPP, TPHP among OPEs, and phenanthrene among PAHs. Concentrations of PBDEs, NBFRs, OPEs and PAHs in wristbands ranged from 0.1 to 6 ng/g band, 0.1 to 10 ng/g band, 0.1 to 200 ng/g band, and 0.1 to 20 ng/g band, respectively. Levels measured in wristbands were generally positively correlated with levels in hand wipes and OVS samples summed together ($p<$ 0.01), confirming our hypothesis. We conclude that silicone wristbands are suitable for quantitative assessment of human exposure to a large range of chemicals simultaneously, and this exposure represents both inhalation and dermal contact.

## Emerging Flame Retardants: State-of-the-Art Knowledge and Addressing Research Gaps

### 350 Two decades of environmental research on flame retardants – taking stock

*J. de Boer, VU University / IVM*

Two presentations at Dioxin1998 in Stockholm on the discovery of polybrominated diphenylethers (PBDEs) in human milk and in sperm whales are considered as the start of brominated flame retardant (BFR) research in the environment and humans at a global scale. Scientists have successfully demonstrated the negative effects PBDEs and hexabromocyclododecane (HBCD), which has resulted in bans of these FRs in many countries. It would be expected that this lesson on the negative effects of these BFRs, following the problems caused by PCBs, would finally lead to a total stop on the production of BFRs and chlorinated FRs. Unfortunately, the current situation is not at all like that. The total global production of FRs increases every year with ca. 4%, including BFRs, while also chlorinated paraffins are still being produced. Meanwhile phosphorous-based FRs (PFRs) have increasingly been produced. The European research project *ENFIRO* showed that some PFRs may be less harmful for the environment. Although bioaccumulation of these PFRs is less than that of BFRs, some chlorinated PFRs do bioaccumulate. The large number of compounds made available and the mixtures that are being used pose new questions with regard to health effects. With bioaccumulation playing a less important role, exposure routes have shifted from food to indoor air and dust due to leaching of the various FRs from electronic equipment and furniture. Currently, authorities in the US and Europe work on restrictions of harmful FRs. At the same time, industry tries to develop alternatives for the ones likely to be restricted in the near future. Halogenated polymers such as brominated polystyrene belong to the alternatives offered as well as halogen-phosphorus FRs such as tris(trisbromoneopentyl) phosphate, di- and tribromoneopentylalcohol, tris(1,3-dichloroisopropyl) phosphate, chloroalkyl-phosphate blends and many others. Many of these alternatives are not environment-friendly. In the 1950s people had 15 minutes available to escape from a fire in their house before a total flashover. Nowadays, in spite of all FRs, this is 3 minutes. The fire brigade still arrives after ca. 8 minutes. It shows that where many FRs have caused a threat to the environment and human health, they have not been able to increase the safety in our homes. It means that this topic still requires much attention, both from the fire safety side as well as regarding negative aspects for the environment and human health.

### 351 Screening Consumer Products for Flame Retardants

*R. Gill, California Environmental Protection Agency; R. Sarala, California Environmental Protection Agency / Environmental Chemistry Laboratory; D.H. Tarrant, S. Takaku-Pugh, California Environmental Protection Agency / California Department of Toxic Substances Control; E. Lytle, California Environmental Protection Agency / Environmental Chemistry Laboratory; F. Brown, J. Park, M. Petreas, California Environmental Protection Agency / Department of Toxic Substances Control / Environmental Chemistry Laboratory*

Flame retardants (FRs) have been added to polyurethane foam, textiles, and other consumer products to meet flammability standards, including California's Technical Bulletin 117 (TB 117). Recent legislation, California Senate Bill 1019 (SB 1019) requires labelling of a product as to whether it does or does not contain added FRs. Samples labelled as not containing FRs were collected and submitted by the Department of Consumer Affairs (DCA). In addition, a second group of samples were collected for a furniture replacement study that included furniture samples pre- and post- SB 1019. Together, over 150 samples were analyzed for added FRs. Energy Dispersive X-Ray Fluorescence (XRF) was used to screen samples for the presence of Bromine (Br), Chlorine (Cl), and Phosphorus (P), key elemental indicators for Brominated Flame Retardants (BFRs) and Organophosphate Flame Retardants (OPFRs). The use of XRF allowed samples to be directly analyzed with limited or no sample preparation, increasing sample throughput and providing data to indicate whether a FR was present at an elevated level and information on the class of FR present. A second screening method using Inductively Coupled Plasma – Optical Emission Spectrometry analysis was performed in parallel to measure the concentration of P. Gas Chromatography – Tandem Mass Spectrometry (GC-MS/MS) was used to measure 17 specific BFRs and OPFRs and demonstrate the utility of the screening techniques. Samples analyzed by GC-MS/MS, were homogenized by cryogenic milling, spiked with labelled surrogates and extracted by three cycles of vortexing and sonication in toluene. Data confirmed the reliability of XRF to rule out BFRs if Br was not detected, as well as OPFRs when Cl and or P were not detected when total FR levels measured by GC-MS/MS were below 500 ppm. XRF was determined to be a rapid and effective screening tool to limit the number of samples requiring quantitative analysis to those that contained total FRs above the 1000 ppm regulatory limit. We also report on the number of mislabeled products that are in violation of SB 1019. A three-year trend post adoption of the SB 1019 labeling requirement shows a decrease in the number of mislabeled products from 30 to 20 percent. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

### 352 Brominated & Organophosphate Flame Retardants along a Sediment Transect Encompassing the Guiyu, China E-waste Recycling Zone

*H. Li, Guangzhou Institute of Geochemistry; R.C. Hale, M.J. La Guardia, Virginia Institute of Marine Science / Aquatic Health Sciences; H. Liu, G. Sheng, P. Peng, Guangzhou Institute of Geochemistry*

E-waste recycling using crude techniques releases a complex, yet incompletely characterized mixture of hazardous materials, including flame retardants (FRs), to the environment. Their migration downstream, possibly traced by their pollution profiles, and potential risks also remains undocumented. We examined 26 FRs (18 brominated (BFRs: 12 polybrominated diphenyl ether (PBDE) congeners, plus 6 alternatives) and 8 organophosphate esters (OPEs)) in surficial sediments of the Lian River. Sampling encompassed the river's origin, through the Guiyu e-waste recycling zone, to its mouth, as well as associated tributaries. OPE exceeded BFR concentrations in most sediments, despite their far greater water solubilities. Among OPEs, tris(1-chloro-2-propyl) phosphate dominated upstream, but shifted to triphenyl phosphate in Guiyu and downstream sediments. For PBDEs, Deca-BDE dominated upstream, but Penta-BDE prevailed in Guiyu and at many downstream sites. Among emerging alternative BFRs, decabromodiphenyl ethane dominated upstream, transitioning to 1,2-bis(2,4,6,-tribromophenoxy)ethane in Guiyu sediments. Penta-BDE (BDE-47 + -99, 668-204,000 ng $g^{-1}$, PBDEs 2,280-287,000 ng $g^{-1}$), tetrabromobisphenol A (2,720-41,200 ng $g^{-1}$), 1,2-bis(2,4,6,-tribromophenoxy)ethane (222-9,870 ng $g^{-1}$) and triphenyl phosphate (4,260-1,710,000 ng $g^{-1}$, OPEs 6,010-2,120,000 ng $g^{-1}$) concentrations in Guiyu sediments were among the highest reported in the world to date. The continuing dominance of these e-waste indicative FRs in downstream of Guiyu suggested that FR migration from Guiyu occurred. Hazard quotients >1.0 indicated that the extreme sediment concentrations of individual FRs posed ecological risks in most areas of the Guiyu reach and downstream. Simultaneous exposure to multiple FRs likely increased risks. However, risks may be lower if FRs were associated with strong sorbents, e.g., carbon black from burned debris, hydrophobic polymer fragments, or resided as additives within polymer fragments.

### 353 Organophosphite Antioxidants in Indoor Dust Represent an Indirect Source of Organophosphate Esters

*R. Liu, S. Mabury, University of Toronto*

Organophosphate esters (OPEs) are a group of massively produced and applied additives, whose concentrations in indoor dust are related to human health. Thus, accurate analysis of OPEs in indoor dust is the precondition to estimate their adverse effects on human health. Previous study always paid attention on OPEs from direct sources. In this study, indirect sources of OPEs were discussed. Organic phosphite antioxidants (OPAs) are among the most frequently used antioxidants in various household and industrial products to retard oxidation degradation. The OPAs can be oxidized to the corresponding OPEs during the antioxidant process. In this study, five OPAs were detected in indoor dust samples, with geometric mean (GM) concentrations of 2.46-70.4 ng/g. The corresponding OPEs were detected at much higher GM concentrations (30.5-3759 ng/g). Among the detected OPEs, triisodecyl phosphate (TiDeP), trisnonylphenol phosphate (TNPP), tris(2,4-di-*tert*-butylphenyl) phosphate (AO168=O), and bis(2,4-di-*tert*-butylphenyl) pentaerythritol diphosphate (AO626=$O_2$) were the oxidation products of the corresponding OPAs, which represents the indirect source of OPEs. The concentrations of the above four novel OPEs (GM: 30.5-3759 ng/g) are even higher than the well-known tris(2-chloroethyl) phosphate (TCEP), triphenyl phosphate (TPP), 2-ethylhexyl diphenyl phosphate (EHDPP), tris(2-ethylhexyl) phosphate (TEHP) (GM: 111-1827 ng/g), which are mainly from direct source. The present study demonstrates that people are exposed to much more OPEs than we previously knew in indoor environments. To our knowledge, this is the first time to report the occurrence of TiDeP, AO626=$O_2$, and TNPP in indoor dust.

**354 Emerging and legacy flame retardants in plasma of pregnant women from a Chinese preterm birth cohort**

*X. Liu, Jinan University; B. Wang, Z. Li, Peking University; D. Chen, Jinan University / School of Environment*

Preterm birth represents a significant public health concern. Among the variety of etiology which remains unknown in many cases, exposure to environmental endocrine disruptors represents a potential risk, but receives less investigations. Flame retardants (FRs) are a group of chemicals broadly added to various household products and some of them (e.g., polybrominated diphenyl ethers or PBDEs) have already been demonstrated to be persistent, bioaccumulative, and toxic. Previous research has discovered the presence of FRs in humans and the associations with a variety of health effects (e.g. thyroid hormone and androgen abnormalities). This study aimed to determine the concentrations and compositions a wide range of FRs in plasma collected during the first or second trimester of pregnancy women. Participants were from a prospective cohort of 4229 women between December 2009 and December 2012 with 147 cases and 381 controls in North China. Up to 70 flame retardant chemicals, including PBDEs, novel brominated flame retardants, dechlorane related compounds, and organophosphorus flame retardants, were analyzed by using a highly sensitive and selective analytical method. Although the study is still under way, our preliminary results revealed the frequent detection of some emerging and legacy flame retardants (e.g. BDE209, decabromodiphenylethane, tris(chloroethyl) phosphate) in plasma. The results of this study will be employed in the near future to further investigate the association of exposure to flame retardants with the odds of preterm birth risks, as well as the influencing factors, in the study cohort.

**355 Quantitative method development of newly discovered highly brominated flame retardants in Great Lakes Herring Gull regurgitant and terrestrial sources**

*T.A. Smythe, Carleton University / Chemistry; G. Su, Nanjing University of Science and Technology / School of Environmental Science and Engineering; L.T. Gauthier, R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division*

Recent reviews and observations have suggested that one trend for replacement brominated organic flame retardants (OFRs) is towards more highly brominated chemicals with higher molecular weights, such as polymer-like polyhalogenated polyphenol ethers (PHPEs). Although large, highly brominated OFRs possess low bioavailability, it has become increasingly evident that photochemical and/or microbial degradation processes can result in the formation of e.g. lower brominated and more bioavailable compounds. Tetradecabromo-1,4-diphenoxybenzene (TeDB-DiPhOBz) is a PHPE with similar molecular structure to BDE-209 and decabromodiphenylethane (DBDPE), and was the principal component of the now phased out SAYTEX 120 FR mixture. TeDB-DiPhOBz is highly sensitive to photodegradation, resulting in the formation of lower brominated DiPhOBzs and polydibenzofurans. These mixtures of degradation by-products have subsequently been shown to induce CYP1A4/5 mRNA in a concentration-dependent manner in vitro in chicken embryonic hepatocytes. Concurrently, methoxylated polybrominated diphenoxybenzenes (MeO-PB-DiPhOBzs) have been reported in Great Lakes Herring Gull (GLHG) eggs from several colony sites and from collections going back over 40 years. Strong evidence indicates that TeDB-DiPhOBz and its debrominated degradation by-products are absent from typical prey fish of GLHGs, and thus aquatic food web exposure appears to be a minor exposure route. As a result, it is hypothesized that the gulls are exposed via their terrestrial diet component. To date, we are the only lab to investigate TeDB-DiPhOBz in an environmental context. Moreover, to our knowledge there have yet to be any published methods investigating OFRs in avian regurgitant (vomit). The current study adapted and validated existing OFR methods for the quantitative determination of TeDB-DiPhOBz and its photodegradation products via LC-/GC-MS, utilizing newly acquired authentic and pure polybrominated-diphenoxybenzene (PB-DiPhOBz) and MeO-PB-DiPhOBz congener standards on three different and novel sample matrices: herring gull regurgitant, the soil surrounding selected nest areas, and earthworms, from Channel-Shelter Island, Saginaw Bay, Lake Huron. Analyses indicate that debrominated PB-DiPhOBz congeners, but not TeDB-DiPhOBz, were detectable in some of the terrestrial samples. Herring gulls appear to be exposed to TeDB-DiPhOBz via their terrestrial diet but in the form of their PB-DiPhOBz degradation by-products.

**356 Transport of sediment borne emerging flame retardants in a Mediterranean river during a high flow event**

*D. Barcelo, ICRA / Department of Environmental Chemistry; A. Herrero, Catalan Institute for Water Research ICRA; J. Vilà-Cano, E. ElJarrat, IDAEA CSIC; A. Ginebreda, IDAEA CSIC / Environmental Chemistry; S. Sabater, Universitat de Girona; R. Batalla, UdL*

Pollutants' dynamics in rivers flowing through industrial areas is linked to the transport of contaminants attached to solid particles. The transport of sediment is mainly associated to high discharges and flood episodes, and these events constitute one of the main factors causing fluxes of buried pollutants in rivers. We performed a field study in the lower River Cinca (Ebro basin, Northeast Spain) to quantify the mobilization and transfer of several contaminants present in the river bed sediments. We focused on legacy POPs such as PCBs, DDXs, PBDEs and HBCDs, but also on emerging flame retardants such as decabromodiphenyl ethane (DBDPE) and organophosphate flame retardants (OPFRs). Static sediment samples were collected and analyzed. Both, legacy and emerging pollutants were detected, but the highest concentrations were found for DBDPE and OPFRs, with concentration values ranging from 7.81-121 and 18.8-127 ng/g dw, respectively. Among the different OPFRs analyzed, the highest levels corresponded to tributyl phosphate (TBP), tris(chloroisopropyl) phosphate (TClPP) and triphenyl phosphate (TPHP). A subsequent sampling campaign was used to capture sediment borne contaminants during a flood event. Water samples were taken at the same locations as the static sediments and used to determine the suspended sediment concentrations and the contaminants content (i.e. mass of contaminant per sediment mass unit) during the event. We estimated mass fluxes for both sediment and pollutants, and determined that sediment transport followed a clockwise hysteresis. This is typically observed in high flow events after dry summer periods. With sediments there was a large mobilization of OPFRs (36 kg in 48 h in one of the main tributaries) and PCBs not previously observed in the static sediment. Observed contaminant load ranges during the two-day sampling campaign were: PCB (34–152 g), DDT (12–213 g), PBDE (50–1740 g), HBCD (0–2.2 g) and OPFR (2410–35,895 g). An environmental risk assessment was carried out by comparing pollutant concentrations found in the sediments with the Canadian quality guidelines (ISQC), showing a significant noncompliance for PCBs in dynamic sediments. Our results point out to the need to include emerging flame retardants in river basin monitoring studies, as well as the need of a regular assessment of the downstream transfer of the sediment-borne pollutants in drainage basins historically affected by intense industrial activities.

**357 Flame Retardant Benefit and Harm: Past, Present, and Future**

*A. Blum, Green Science Policy Institute; M.L. Diamond, University of Toronto / Department of Earth Sciences*

Flammability regulations for furniture and foam plastic building insulation were established in North America in the 1970s in an attempt to reduce fire deaths and losses. Flame retardant (FR) chemicals have been used to meet these regulations, but their use has been found to be questionable based on a lack of proven fire safety benefit; potential for FR migration from products resulting in human and ecosystem exposure and adverse health effects. For major product categories, we will discuss the current status of flammability standards driving the use of FRs and whether on not they provide a fire safety benefit to balance their adverse impacts. Upholstered Furniture had metthe California furniture flammability standard Technical Bulletin 117 (TB117) since 1975, which led to FRs in upholstered furniture foam. In 2013, California updated their standard to TB117-2013, which increased fire safety from smoldering ignitions without the need for FRs. In 2017, the US Consumer Product Safety Commission approved a petition to ban the entire class of organohalogen FRs in upholstered furniture and three other products classes. Several US cities and states are banning all FRs in furniture, juvenile products, and/or mattresses. Foam Plastic Building Insulation materials are affordable and energy efficient, but flammable. US and Canadian building codes lead to the use of FRs in such insulation, but they do not improve fire performance of insulation below grade or within a wall cavity behind a thermal barrier. Norway has updated their flammability codes so that FRs are no longer needed in such applications. Similar changes are being considered in the U.S. Electronics suchas televisions cases are one of the biggest sources of FR exposure in our homes with FR concentrations around 25% of the weight of the plastic. A new international fire safety standard allows the redesign of TVs and other electronics so that cases are fire safe without the need for FRs. Conclusion: New policy decisions and regulations based on toxicological and fire science research are considering both fire safety and the health and ecological impacts of FRs. This approach is reducing exposure to harmful FRs. However, in some cases organophosphates FRs are being used instead of organohalogens—a likely “regrettable substitution.” Improving flammability standards is a better way to reduce the unneeded use of FRs compared to moving to the use of replacement FRs which may also prove to be harmful.

## Canadian Oil Sands: Advancing Science in Chemical and Toxicological Characterization, Reclamation and Monitoring

**358 Nontarget screening and characterization of polar polycyclic aromatic hydrocarbons in samples from the Athabasca Oil Sands using LC-Orbitrap-MS**

*L. Chibwe, Environment and Climate Change Canada / Aquatic Contaminants Research Division; C.A. Manzano, Universidad de Chile / Department of Chemistry; D.C. Muir, B. Atkinson, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Kirk, Environment and Climate Change Canada / Global Tox; A.O. De Silva, Environment and Climate Change Canada / Aquatic Contaminants Research Division*

Polycyclic aromatic compounds (PACs) are a group of organic contaminants associated with the Athabasca Oil Sands region (AOS) in Alberta, Canada, although more work is needed to understand the relative contributions of various industrial sources to levels of these compounds to the environment s. Furthermore, even though PACs exist in complex mixtures, environmental monitoring in the AOS is often focused on a limited class of, mostly unsubstituted and alkylated PACs, and may fail to account for the more polar PACs that can be as, if not more, toxic. In this study, a nontarget screening approach using liquid chromatography HR-Orbitrap mass spectrometry was used to identify and characterize the distributions of polar N, S, O-containing PACs in snow, air, sediment, and source materials (i.e. petroleum coke, unprocessed oil sands ores, and haul road dust) from the AOS. Because of the excessive data generated from HR-Orbitrap analysis, steps were taken to prioritize PAC-characteristic compounds from the thousands of other peaks detected. Elemental compositions were determined based on accurate mass (< 5ppm) and isotopic abundances. Peaks were refined if they had relative double bond equivalencies between 6 and 18, elemental compositions containing 6< C< 30, and at most 2 S/O/N atoms. Kendrick mass defect plots (KMDs) and MS/MS were used to support and further refine elemental composition assignments. Additionally, KMD plots were able to provide a “fingerprint” profile, showing distinctions between the source samples, and similarities between pet coke and the environmental near-field samples, suggesting pet coke is a potentially important source. Relative distributions based on the normalized areas of detected peaks also confirmed pet coke as the source, as there were similarities in distribution between the pet coke and the environmental samples near major developmental areas. Over 25 “families” (elemental compositions) of polar PACs were detected, including “families” of nitrogen and sulphur-containing PACs previously detected in AOS environmental samples using GCxGC/ToF-MS. This study suggests that further work is needed in characterizing these compounds in the AOS, and that the orbitrap is a useful technique in providing a comprehensive screening and profiling of these compounds.

**359 What does an Athabasca Oil Sands tailings pond plume look like?**

*P. Gammon, J.M. Ahad, Natural Resources Canada / Geological Survey of Canada; R. Amos, S. Morton, Carleton University; S. Roussel, PBW Consulting; M. Savard, Natural Resources Canada / Geological Survey of Canada*

What is the chemical fingerprint of Athabasca Oil Sands Industry tailings pond waters (TPW) that have escaped into surrounding environments? Many studies and most industry monitoring have used chloride in particular, but also boron and to a lesser extent naphthenic acids (NAs), as conservative ion tracers to infer TPW input. A few have successfully used advanced isotopic data. However, most studies generally lack sufficient detail to infer specific pathway(s) or defined input structure(s). The Environmental Geoscience Program of the Geological Survey of Canada has erected a detailed (38 well and drive points) dataset of hydrology and geochemistry (elemental, organic and isotopic) on a small (100 m by 160 m) test site adjacent to the Muskeg River and down-hydraulic-gradient from a large tailings pond. Along the southwestern boundary of this site is a subsurface conglomeratic aquifer that hosts waters having $d^2H$ and $d^7Li$ isotopic signatures indicating a TPW origin. Aquifer waters have concentrations of B and Li that are 5X to 10X background values, concentrations that are consistent only with a TPW source. Element concentration distributions indicate the aquifer is confined at depth. However, at the southwestern edge of the study area these waters surface and spread across the adjacent wetland, resulting in atypical wetland vertical profiles having higher concentrations at the surface than at depth. The distributions of Be, Cr, F, Rb, V, U, Zr are also consistent with an introduction into subsurface and surface waters via this aquifer. Conversely, chloride and sodium increase away from the aquifer; their molar ratio and distribution demark these as predominantly reflecting road salt inputs. In comparison to TPW concentrations, the aquifer waters are highly diminished (>5X for conservative ions; complete attenuation for many transition metals). Within the site, the aquifer-introduced elements demonstrate considerable and variable attenuation along the flow path (3X to full attenuation); a product of both dilution and sorption as B-normalised contours demonstrate. The combined attenuation profiles produce element concentrations below CCME guidelines throughout the site. The TPW chemical fingerprint has not been detected in the Muskeg River itself, suggesting that the aquifer flux is relatively small.

**360 Temporal variation and source apportionment of snowpack multi-elements deposition in the Athabasca Oil Sands Region**

*Y. Gopalapillai, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Kirk, Environment and Climate Change Canada / Global Tox; M. Landis, Integrated Atmospheric Solutions LLC; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; D. Schindler, University of Alberta; E. Kelly, Government of the Northwest Territories; C. Cooke, Alberta Environmental Monitoring, Evaluation and Reporting Agency*

Atmospheric deposition of metals in snowpacks and their release into freshwaters during spring snowmelt has been a concern in the Athabasca Oil Sands Region of Alberta. This study was designed to evaluate the concentrations, loadings, and distribution of metals in springtime snowpack and how they vary over time. For a few metals (Al, V) we investigate temporal data as early as 1978 and into 2016. For the remaining suite of metals, we examine several years of data (2008-2016) collected through a rigorous monitoring program, the Joint Oil Sands Monitoring (JOSM) program. Snowpack samples were collected in late winters at varying distances from the main developments. For data from 1978 and 1981 to be comparable to newer data, all metal loads were adjusted to the same number of snow days. Temporal trends were divided into sites less than 8 km from a major industrial site (AR6), 8-50 km from AR6, 50-100 km from AR6 , and reference sites >100 km northeast of AR6. Results indicate that deposition of metals generally decreased over time. Source apportionment indicates that AR6 appears to be the main industrial source for V, but smaller impact of other sources was evident for other elements. Further monitoring is required to ensure that the impact of metals is understood.

**361 Effects of Contaminated Snowmelt from the Athabasca Oil Sands on the Growth, Development and Behaviour of Larval Wood Frogs (Lithobates sylvatica)**

*S.A. Patterson, Queens University / Department of the Enviornmental Studies; J. Kirk, Environment and Climate Change Canada / Global Tox; C. Davy, Ontario Ministry of Natural Resources and Forestry; B. Pauli, Environment and Climate Change Canada / National Wildlife Research Centre; V.L. Trudeau, J.M. Blais, University of Ottawa / Biology; D.M. Orihel, Queens University / Department of Biology / School of Environmental Studies; L. Chen, Queens University*

Oil sands operations in northern Alberta, Canada, are major emitters of atmospheric pollutants, including polycyclic aromatic compounds (PACs) and heavy metals. Previous studies have documented elevated levels of atmospheric pollutants in snowpack within a 50-km radius of two major bitumen upgrading facilities. Amphibians inhabiting wetlands in northern Alberta during spring may be at risk of exposure to pulses of contaminants from melting snow. The goal of our study was to assess the effects of snow contaminated by oil sands operations on the growth, development, and behaviour of a common amphibian species, the wood frog (*Lithobates sylvaticus*). We conducted an outdoor mesocosm experiment at the Queen's University Biological Station in which wood frog embryos were exposed to snow collected from the Athabasca Oil sands region. Snow was collected from three impacted sites (< 50 km from upgraders) and three reference sites (> 83 km from upgraders). Snowmelt treatments were compared to a negative control (natural pond water) and an osmotic control (natural pond water diluted with distilled water). Each of the six snowmelt treatments and the two controls were replicated three times. Wood frog tadpoles were exposed to snowmelt for 25 days, and then were transferred to a clean water environment for an additional 55 days, to simulate the flushing effects of spring rains. Each replicate contained ~250 embryos in the exposure phase and 20 tadpoles during the clean growth phase. We measured tissue PAC concentrations, malformations, expression levels for several genes related to development, body length, body weight, developmental stages and growth rates. Concentrations of PACs in wood frog tadpoles after the 25-day exposure to snowmelt ranged from 272.186 to 2.270 mg/L in the impacted sites and 2.385 to 2.640 mg/L in the reference sites. During the exposure period, tadpoles exposed to snowmelt from impacted sites (0-km and 6-km) showed decreased average body lengths and an increased presence of morphological malformations (gut coiling and body shape). Contrarily, at the end of the clean growth phase, body lengths, body weights and developmental rates of tadpoles from snowmelt treatments were similar to those from the controls.

**362 Sediment-bound dilbit: Comparing direct exposure to the water-soluble fraction on the health of freshwater amphipods (*Hyalella azteca*)**

*S. Everitt, University of Lethbridge / Department of Biological Sciences; S. Wiseman, University of Lethbridge / Biology; G.G. Pyle, University of Lethbridge / Biological Sciences*

The Alberta oil sands contain over 165 billion barrels of bitumen. Bitumen is transported as diluted bitumen (dilbit) after the addition of natural gas condensates. Dilbit is transported predominantly through pipelines, which come in close proximity to freshwater ecosystems. When dilbit is spilled into or near an aquatic environment, much of the volatile added diluents will evaporate, increasing the density of the dilbit. The remaining weathered dilbit has the potential to combine with fine sediment in the water column and sink permanently, affecting different organisms than if it were to remain on the surface. Weathered sediment-bound dilbit (WSD) can be physically toxic to freshwater organisms by coating them or chemically toxic by releasing water-soluble toxicants such as polycyclic aromatic hydrocarbons and their alkylated counterparts. To date, research has focused on the water-soluble and water-accommodated fractions of fresh dilbit and its effects on aquatic organisms. This is the first study that assesses the toxicity of WSD to an aquatic organism. Substrates were formulated that were 100, 50, 25, 12.5 and 6.25% WSD by volume. Adult freshwater amphipods (*Hyalella azteca*) were exposed to these concentrations of WSD for 96 hours. In all concentrations of WSD, there was 0% survival. Additional exposures have shown that the water-soluble fraction of WSD does not negatively affect survival during acute exposure. Ongoing research is addressing if the water-soluble fraction of WSD will alter amphipods physiologically by inducing acetylcholinesterase inhibition, oxidative stress or by altering oxygen consumption. Behavioural experiments are also being conducted to determine if the water-soluble fraction of WSD can change the overall activity of amphipods as a result of these physiological changes. This study shows that different fractions of dilbit may have varying effects on freshwater organisms, which will help to inform for better cleanup practices after future dilbit spills.

**363 PAH concentrations and composition in predatory and forage fish in the Fort McMurray oil sands area with comparisons to environmental regime**

*M. Evans, Environment and Climate Change Canada / Water, Science and Technology; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology / Aquatic Contaminants Research Division; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; H. Keith, Hatfield Consultants; G. Tetreault, Enviroment Canada / Water Science and Technology; J. Keating, Environment and Climate Change Canada / Water and Science Technology*

The Fort McMurray region is rich in natural sources of polycyclic aromatic hydrocarbons (PACs) from exposed bitumen beds; anthropogenic sources have increased with oil sands industry expansion and PACs have been monitored and investigated in several environmental compartments. Here we present highlights of our broad survey of PACs in four species of forage and predatory fish investigated as part of fish health investigations conducted as part of the Regional Aquatics Monitoring Program (RAMP) and the Joint Oil Sands Monitoring program. We also compare fish PAC concentrations and composition with that observed in sediment

and water samples collected as part of these monitoring programs. PAC concentrations in fish, water and sediments were highest at those downstream tributary mouths which flowed through the exposed McMurray formation and along the Athabasca River. ΣPACs averaged 102±32 ng/g (68± 5% alkylated) in trout-perch from the Athabasca River; 278±267 ng/g (75± 13% alkylated) in slimy sculpin from the Steepbank, Firebag, and Dunkirk Rivers; and 125±22 ng/g (64±6% alkylated) in lake chub from the Ells River. ΣPACs concentrations were lower in walleye from the Athabasca River (18±21.6 ng/g, 60±24% alkylated) with still lower concentrations in walleye from Lake Athabasca (1±1 ng/g, 31±27% alkylated) and the Peace River (7±6 ng/g, 65±13% alkylated). Fish ΣPACs were dominated by low-molecular weight compounds, particularly naphthalenes and fluorenes whereas medium and heavy PACs such as dibenzothiophenes, fluoranthenes, pyrene and chrysene, common in sediments, were minor contributors. Phenanthrenes increased in percent composition in fish caught in areas where PACs concentrations in sediments were higher due to the proximity of bitumen sources; dibenzothiophenes, a major component of bitumen PAC, were a minor component of fish PACs. Fish PACs concentrations were below the European Commission (2011) smoked fish consumption guideline of 2.0 ng/g for benzo(a)pyrene and 12 ng/g for the sum of benzo(a)pyrene, benz(a)anthracene, benzo(b)fluoranthene, and chrysene. Fish PAC concentrations also were below guidelines established for the reopening of the commercial fisheries closed by the Deepwater Horizon oil spill. PAC concentrations in fish were similar to concentrations observed in other studies including fish market surveys, estuaries, and marine waters and lower than in highly impacted areas near refineries and other anthropogenic sources of PACs.

### 364 Effects Directed Analysis of Soluble Organics in Bitumen Influenced Waters

*M.R. Rodrigues, University of Waterloo / Biology; M. Hewitt, Environment and Climate Change Canada / Canada Centre Inland Waters; R. Frank, Environment Canada / ACRD; G. Dixon, University of Waterloo / Department of Biology*

Identification of the organic compounds of concern within bitumen-influenced waters is critical for effective monitoring and reclamation within Canada's oil sands region. Effects directed analysis provides an effective tool to prioritize bioactive and unique compounds of interest in industrial and natural bitumen-influenced waters, allowing for chemical and toxicological characterization of less complex mixtures relative to unaltered waters. Recently identified bioactive fractions from bitumen-influenced groundwater sources were further fractioned using HPLC. The isolated secondary fractions were analyzed using an LC/QToF- MS, indicating successful fractionation with decreasing polarity with subsequent fractions. Toxicity was assessed using the Microtox® assay and *Hyallela azteca*; these assays were selected due to previous responses observed using the primary groundwater fractions. Assays with *H. azteca* required the development of a reduced volume test protocol due to limited secondary fraction volume. The Microtox® and *H. azteca* assays were sensitive to the most polar of the secondary fractions isolated from the most polar primary fractions, further indicating that toxicity is at least in part being driven by the most polar chemical constituents.

### 365 Process-Affected Water in the Oil Sands Industry: Toxicity Attribution and Evaluating Ageing as a Remediation Strategy

*I. Gault, University of Alberta / Laboratory Medicine & Pathology; B. Moe, Alberta Centre for Toxicology; C. Sun, University of Alberta / Laboratory Medicine & Pathology; J.W. Martin, University of Alberta / Department of Environmental Science and Analytical Chemistry (ACES)*

Oil sands process-affected water (OSPW) is used to separate bitumen from sand in the surface-mining oil sands industry of Alberta. OSPW contains a complex dissolved organic mixture that can be toxic, persistent, and is largely uncharacterized. One remediation strategy consists of ageing OSPW in end-pit lakes such that sedimentation and biodegradation of the organics through ageing will eventually allow for safe environmental integration. Predicting the effectiveness of this strategy relies on an understanding of what chemicals cause toxicity in fresh OSPW and how these may change over time. This investigation used chemical fractionation and high resolution orbitrap mass spectrometry combined with cytotoxicity and endocrine disruption assays to further study the toxicity of candidate chemical classes in various fresh and aged OSPW samples. Real-time cell analysis of human liver carcinoma cells (HepG2) and the yeast estrogenic/androgenic screens were used. An isolated fraction containing naphthenic acids (NAs) was largely responsible for the cytotoxicity observed, while the non-acidic fraction, speculated to contain steroidal chemicals, was not cytotoxic. Estrogen/androgen receptor antagonists were identified in all the fractions, with both NAs and the non-acidic fractions active near environmentally relevant concentrations, though chemical antagonism is known to exist within the mixture. Cytotoxicity of OSPW in an end-pit lake decreased as the sample was further aged. However, an even older sample of 23 years that is geographically-separate from the end-pit lake had a unique biphasic toxicity profile, where the organics were initially more cytotoxic than the other OSPW samples tested around 24 hours' post exposure, but then the cells recuperated to close to negative control around 60 hours' post exposure. Therefore, cytotoxicity of an end-pit lake decreased with ageing, which is promising for the remediation strategy, but the biphasic toxicity profile from the most recalcitrant organics should be explored. Furthermore, while NAs were responsible for the cytotoxic effect, the presence of estrogen/androgen receptor antagonists among all the fractions indicate that multiple chemical classes may have the potential for sub-lethal effects on the endocrine system. By identifying the most active chemicals in OSPW there can be a better understanding of observed toxic effects and allow for monitoring to ensure releases are protective of downstream uses.

## Ecotoxicology of Amphibians and Reptiles

### 366 A generalized lizard population model to investigate the impact of toxicity on reptile population dynamics

*S.M. Weir, Queens University of Charlotte / Biology; C.J. Salice, Towson University / Environmental Science & Studies Biology*

There is an interest in putting toxicity data into a population context, with some authors suggesting that population growth rate (or lambda) is an equally important endpoint to consider in ecotoxicology along with effects on survival and reproduction. For the purposes of screening level risk assessment, it would be very helpful to have a generalized population model into which toxicity data can be incorporated to understand the long-term implications of repeated toxicity events. We report on a generalized deterministic lizard population model for *Sceloporus sp* parameterized from demographic data collected from the literature. Our model is a simple 2 stage model with a juvenile stage (1 year) and an adult stage. Because there is so little toxicity data available for reptiles and even less data on their exposure to contaminants in the field, we performed theoretical simulations of 0 to 100% toxicity to each stage of the model (clutch size, juvenile survival, adult survival). We quantified the effects of toxicity on lambda and elasticity values for each stage. The baseline model has a stable population with lambda = 1.07. The fecundity and juvenile survival parameters had the greatest effect on population dynamics. When we applied simulated reductions in survival and clutch size all models showed a decrease in lambda with increasing toxicity. A 20% yearly reduction in juvenile survival or clutch size resulted in lambda decreasing below 1.0 into a slight population decline, while a 30% reduction was needed in adult survival for the same result. Lambda generally was reduced more when juvenile survival or clutch size was impacted. Elasticities changed significantly only when there was high toxicity to juvenile and fecundity estimates (> 60% yearly mortality) at which point adult survival became the most important parameter in the model. Our model suggests that reptile populations are robust to a slight decrease in yearly survival, but repeated reductions in survival will threaten population persistence. This highlights the importance of both quantifying toxicity to these taxa, but also understanding how often exposures occur and if there is any risk of mortality from those exposures. Next steps for the model are shifting the model from a deterministic model to a stochastic model incorporating parameter variation which could be useful for a higher tier risk assessment when risk is found at a lower tier.

**367 Exposure and Effects of common perfluoroalkyl substances (PFASs) on Brown Anoles (*Anolis Sagrei*)**

*C. Weible, Towson University; A. East, Towson University / Environmental Sciences; C.J. Salice, Towson University / Environmental Science & Studies Biology*

Per-and polyfluoroalkyl substances (PFASs) are persistent and abundant environmental contaminants, creating concern about their potential ecotoxicological effects on wildlife. The goal of this research was to investigate the impacts of two specific PFASs, perfluorooctanesulfonic acid (PFOS) and perfluorohexane sulfonate (PFHxS), on a model reptilian species. These PFASs were key ingredients in aqueous film forming foam which was widley used for fire suppression at military installations. Fire suppression activities and use in many commercial products have lead to releases of these chemicals into the environment where wildlife can be exposed. While there is some data on the effects of a small subset of PFASs on common ecological receptors, there is no data available on the toxicity of PFOS or PFHxS to reptilian species precluding a robust assessment of risk to species in this taxa. To address this data gap, we have begun developing brown anoles (*Anolis Sagrei*) as a viable laboratory model as they are abundant, non-native species in the U.S. and amenable to laboratory conditions. We first dosed lizards with PFOS using a pseudo-gavage method three times each week for a total of 35 days. A total of 40 lizards were used with 10 animals per dose which were 0, 0.02, 0.2, or 2 mg/kg per day. Dosing volumes were adjusted based on the weekly weight of each lizard. There were no lizard deaths during the 35 day study but there were significant dose-related effects on growth. All lizards were also necropsied and organs weighed. We found that as PFOS concentration increased, spleen and kidney masses increased. To our surprise, lizards in this study appeared to be similarly sensitive compared to avian receptors that had been exposed to PFOS in a reproductive study. We have subsequently initiated a PFOS exposure study in which lizards have been exposed for 30, 60 or 90 days to PFOS-contaminated sand. The goal is to determine whether dermal exposure for PFOS is a relevant exposure pathway. We have also initiated a pseudo-gavage study to determine whether PFHxS is toxic to lizards at high-end environmentally relevant concentrations. We anticipate that the data developed from these studies will facilitate ecological risk assessments focused on the risk of PFASs to reptilian receptors in PFAS-contaminated habitats.

**368 Assessing the effects of per- and polyfluoroalkyl substances on larval amphibians**

*R.W. Flynn, Purdue University / Forestry and Natural Resources; M. Chislock, State University of New York / College at Brockport / Environmental Science and Ecology; G. Hoover, S. Abercrombie, M. Iacchetta, Purdue University / Forestry and Natural Resources; B. Tornabene, The University of Montana; S. Guffey, Purdue University / Forestry and Natural Resources; L.S. Lee, Purdue University / Department of Agronomy; J.T. Hoverman, M.S. Sepulveda, Purdue University / Department of Forestry and Natural Resources*

Per- and polyfluoroalkyl substances (PFASs) are globally distributed contaminants of emerging concern due to their persistence in the environment, accumulation in humans and wildlife, and ability to disrupt endocrine function. The risk posed by these compounds is not well characterized for most wildlife including amphibians. Using a series of laboratory experiments, we examined accumulation and toxicity of perfluorooctanoic acid (PFOA), perfluorooctane sulfonate (PFOS), perfluorohexane sulfonate (PFHxS), and 6:2 fluorotelomer sulfonate (6:2 FTS) to larvae of the American toad, *Anaxyrus americanus*, northern leopard frog, *Lithobates pipiens*, and eastern tiger salamander, *Ambystoma tigrinum*. In general, all PFAS compounds reached steady state concentrations within two days of initial exposure. Mean bioconcentration factors were similar among species, but varied among compounds, from 1 (PFOA, PFHxS, and 6:2 FtS) to 100 (PFOS). Larvae exposed to individual PFASs for 30 days (10 to 1000 ppb) exhibited a 3-10 % increase in snout-vent length relative to the controls, but time to metamorphosis was not affected (toads only). The lack of developmental effects was likely a consequence of the duration of our initial assays, which did not encompass metamorphic climax for most of the species tested. We also conducted an experiment to assess the potential influence of PFAS mixtures (PFOS and PFOA) on larval growth in bullfrogs (*Lithobates catesbeianus*). In this longer 72-day study, we found that PFASs generally acted additively to suppress the growth of larvae, suggesting that adverse effects of mixtures might be predictable based on total PFAS concentration. Given the additive nature of some PFASs and our observations of growth effects at 10 ppb, there appears to be potential for adverse outcomes in surface waters where median PFAS concentrations exceed 10 ppb. Further, we observed significant developmental delays associated with the lowest PFOS concentration tested (i.e. 144 ppb), but not PFOA up to 288 ppb. Our results indicate that PFASs have the potential to negatively impact amphibian growth and development at sublethal concentrations. We are currently incorporating semi-realistic mesocosm and field sampling approaches to develop a more comprehensive understanding of the risk posed by PFASs. Together, these studies will allow us to assess how realistic environmental exposures translate into population-level effects for native amphibians.

**369 Comparison Between the Sensitivities of USEPA Endocrine Distruptor Screening Program's Tier 1 and Tier 2 Amphibian Assays Using Select Chemicals**

*A. Kamel, S.R. Matten, USEPA / Office of Science Coordination and Policy; S.G. Lynn, USEPA / Endocrine Disruptor Screening Program*

The US Environmental Protection Agency, Endocrine Disruptor Screening Program uses a two-tiered approach for screening chemical substances for their potential effect on endocrine systems. The determination whether to require additional Tier 2 testing is made on a weight-of-evidence basis considering data from the Tier 1 assays and other scientifically relevant information that may be available. Three widely used chemicals: 2-ethylhexyl 4-hydroxybenzoate (2-EHHB), 4-nonylphenol-branched (4-NP), and triclosan (TCS), which were selected based on USEPA ToxCast estrogen and androgen receptor in vitro bioactivity data, were subjected to a 21-day Amphibian Metamorphosis Assay (AMA) "Tier 1" and an approximately 16-week Larval Amphibian Growth and Development Assay (LAGDA) "Tier 2". Nieuwkoop and Faber (NF) *Xenopus laevis* larvae at NF stage 51 for AMA and NF stage 8-10 for LAGDA were exposed to 4 test concentrations and a water control. We evaluated the following endpoints during the exposure: mortality, growth (snout-to-vent length (SVL) and body weight), development, morphological features (thyroid, gonad, gonadal ducts, liver and kidney histopathology), overt toxicity, and behavior. We compared the AMA results for TCS from the open literature with the LAGDA results obtained in this study. The AMA studies for the 3 chemicals show no treatment-related effects associated with thyroid-mediated development and no significant histopathologic findings in the thyroid at the tested concentrations. In contrast, LAGDA studies show that the 3 chemicals appear to delay metamorphosis in a concentration-dependent manner, except TCS where the effect is only detected at the highest tested concentration. LAGDA studies also show that there is no effect on growth for TCS and 4-NP, however significant increases in body weight and SVL in NF stage 62 larvae for 2-EHHB were noted. There were no treatment-related findings in the thyroid glands of NF stage 62 frogs exposed to 2-EHHB and 4-NP, however an increase in the prevalence of follicular cell hypertrophy at the minimal severity level was noted in the thyroid glands of frogs exposed to TCS as compared to water controls. It is unclear whether these abnormal morphological features related to exposure to TCS were caused by an endocrine-mediated mechanism. *The findings and conclusions in this abstract have not been formally disseminated by the Agency and should not be construed to represent any Agency determination or policy.*

**370 Altered development of the grass frog (*Rana temporaria*) as a consequence of fungicide induced modifications of food quality**

*J.P. Zubrod, T. Wernicke, M. Konschak, P.T. Baudy, C. Bruehl, R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Institute for Environmental Sciences / University of Koblenz-Landau / Department of Aquatic Sciences and Assessment*

Amphibians are threatened worldwide, while stressors of anthropogenic origin such as pesticides seem to be a driving force. Although direct effects are rather frequently assessed, indirect effects of chemicals through an altered nutritious quality of leaf litter for tadpoles have been largely ignored. As the nutritious quality of leaf litter depends on its microbial conditioning, fungicide exposure might induce indirect effects on the larval stage of frogs, such as the grass frog *Rana temporaria*. To assess for such indirect effects, larvae of *R. temporaria* (n=33) were fed over 11 weeks with black alder leaves either leached for 2 days, or conditioned in absence or presence of a fungicide mixture (azoxystrobin, carbendazim, cyprodinil, quinoxyfen and tebuconazole; sum concentration=100 µg/L) for three weeks prior to their introduction into the experiment. Leaves conditioned in presence of the fungicide mixture exhibited a fungal biomass approx. 30% lower relative to the fungicide free control. The consumption of both the leached and the fungicide exposed leaf material caused an elevated feces production (up to 65%) of *R. temporaria*, whereas leaf consumption of the larvae was 20% increased only when leached leaves were offered. These lower food qualities ultimately resulted in a reduced growth (up to 20%). At the same time, metamorphosis was initiated earlier, indicating a potential active avoidance of hostile environmental conditions during the frogs' aquatic life stage. Additional physiological analyses are planned to foster a mechanistic understanding for the observed effects. nonetheless Our data indicate the potential of fungicides to induce indirect effects in frog larvae through the modification of the nutritious quality of leaf litter.

**371 Effects of Road De-Icing Salt (NaCl) and Temperature on Survival and Growth of Larval Anurans (*Lithobates clamitans* & *L. sylvaticus*)**

*F. Green, Towson University / Environmental Science and Studies; P. Ribeiro, A. East, Towson University / Environmental Sciences; C.J. Salice, Towson University / Environmental Science & Studies Biology*

An important challenge in amphibian ecotoxicology and conservation is that naturally occurring amphibian populations experience multiple, simultaneous stressors while toxicity tests are usually limited to a single stressor. Amphibian populations in the Mid-Atlantic region, for example, are likely experiencing combined effects of several regionally important stress factors. About 14 million tons of road de-icing salts are used each year in North America with NaCl accounting for 98% of total salt use and, hence, increased salinity is an important environmental stressor to aquatic organisms, including amphibians. As well, higher temperature as a result of climate change is also becoming an increasingly important environmental stressor for amphibians. Unfortunately, there are no data on the combined effects of salinity and temperature on amphibians which can hinder any amphibian conservation efforts in the region. To address this important data gap, we are conducting acute and sub-chronic toxicity tests to explore impacts of these two stressors on two common anurans, the wood frog (*Lithobates sylyaticus*) and the green frog (*L. clamitans*). An acute toxicity test was conducted to determine an NaCl $LC_{50}$ (2587.5 mg $Cl^-$/L), and the results were used to inform the treatment levels of the sub-chronic and chronic tests. In the first sub-chronic NaCl exposure study, we exposed green frog larvae to three temperatures (18, 22, and 25 °C), and three concentrations of sodium chloride (500, 1000, and 2000 mg $Cl^-$/L) for 35 days. The larvae were observed daily for mortality and Gosner stage, as well as length and mass of surviving animals. While there was no significant effect of temperature on mortality ($F_{2,36}$ = 2.984, P = 0.0632), there was a significant effect of chloride ($F_{3,36}$ = 48.029, P = 1.14x$10^{-12}$), and no significant interaction effect was observed ($F_{6,36}$ = 0.954, P = 0.4670). Mortality of individuals in the higher mg $Cl^-$ /L treatment group was significantly higher than that of controls and other treatment groups (2000 mg/L > 1000 mg/L = 500 mg/L = 0 mg/L). The experiments with larval wood frogs are currently ongoing but show similar levels of sensitivity to NaCl compared to the experiments on green frog larvae. These studies provide important insights into effects of multiple environmentally relevant anthropogenic stressors on commonly occurring Maryland amphibians and will likely point to NaCl thresholds relevant to environmental management.

**372 Determination of mechanisms of toxicity of legacy brine contamination to amphibians**

*H.J. Puglis, B.K. Kunz, USGS / Columbia Environmental Research Center; P.F. Henry, USGS / Patuxent Wildlife Research Center*

The Williston Basin, North Dakota, has been a leading producer of oil and gas for decades. Brine, water co-produced during the production of oil and gas, has contaminated both the surface and ground water in the area through historical disposal practices and accidental releases. Much of the Williston Basin is included in the Prairie Pothole region, which is pocketed with wetlands that are home to many amphibians. These amphibians play a crucial role in wetland ecosystems by cycling nutrients between the aquatic and terrestrial environment and serving as both predators and prey in the wetland food web. During the aquatic portion of their life cycles, many amphibians in Williston Basin wetlands are potentially exposed to brine contamination, typically marked by high concentrations of total dissolved solids, sodium, and chloride, yet little is known about the toxicity of brine to amphibians. To determine if the ion mixture associated with brine contamination was responsible for mortality observed in previous work, we exposed boreal chorus frog tadpoles (*Pseudacris maculata*) to 1 of 4 reconstituted water treatments for two weeks. The water was mixed to mimic water from a reference wetland and a brine contaminated wetland. Additional treatments included the brine contaminated wetland water spiked with NaCl to 1000 or 2000 mg/L Cl to understand whether chloride was driving the response. Endpoints evaluated included mortality and behavior of the tadpoles as well as measures of biochemical stress. These data clarify the relative importance of chloride in driving toxic effects of brine to help with risk management of waters from oil and gas operations and inform future restorations of amphibian habitat.

**373 Exploring the amphibian exposome in an agricultural landscape using telemetry and passive sampling**

*K.L. Smalling, USGS / NJ Water Science Center; J.E. Swanson, Iowa State University; E. Muths, USGS; C.L. Pierce, S.J. Dinsmore, Iowa State University; M. Vandever, USGS; M.L. Hladik, USGS / California Water Science Center*

Pesticides are one of multiple stressors that contribute to amphibian declines, but their population-level effects are still poorly understood. To determine effects, we must have a better understanding of the route, timing, and rate of exposure under field conditions for various amphibian species. The exposome is defined as a measure of an individuals exposure to all stressors from birth to death and how those exposures relate to health. Understanding the complex relationships among amphibians, pesticides, and their environments is vital for conservation, and investigations into pesticide exposure in the field is a central piece of this puzzle. Specifically, to design mitigation strategies, we need to know where (habitat type) and when (seasonally) individuals are at the highest risk of pesticide exposure. We designed the first field study of its kind that combined radio telemetry, passive samplers, and pesticide accumulation in tissues to characterize the amphibian exposome as it relates to pesticides. Understanding how habitat drives exposure in individuals (i.e., their exposome), and how that relates to individual health is critical to managing species in an agricultural landscape where pesticide exposure is likely. We radio-tracked 72 northern leopard frogs (*Lithobates pipiens*) in two agricultural wetlands to understand where and when individuals are at the greatest risk of pesticide exposure. Novel silicone passive sampling devices (PSDs) were deployed at sites where telemetered frogs were located, then moved to subsequent locations as frogs were radio-tracked. Pesticide concentrations in PSDs varied by habitat and was greatest in agricultural fields where frogs were rarely found. Pesticide concentrations in frogs were greatest in spring when frogs were occupying wetlands compared to late summer when frogs occupied terrestrial habitats. Our results indicate that habitat and time of year influence exposure and accumulation of pesticides in amphibians. Our study illustrates the feasibility of quantifying the amphibian exposome to interpret the role of habitat use in pesticide accumulation in frogs to more effectively conserve amphibians in agricultural landscapes.

## Advancing the Adverse Outcome Pathway Concept for Mitochondrial Dysfunction

### 374 Mitochondrial responses for exploring heterogeneous resolutions of contaminant bioavailability using cell-based in vitro assays

*Z. Wang, Jiangxi University of Science and Technology*

With the intensive developments induced by rapid industrialization and extensive urbanization, increasing amounts of anthropogenic chemical contaminants have been continuously discharged into aquatic environments. While using traditional methods, which are mostly based on the chemical analysis alone of extracted samples from environmental and biological matrixes, it is difficult to accurately determine the bioavailability of contaminants and then reflect their cell-based effects as well as subsequent toxicity risks. Therefore in this study, understanding the degrees of contamination and pollution characteristics regarding of entirely environmental matrix and biological samples in the selected study sites and successfully culturing the primary cells from critical tissues in aquatic organisms of ecological niche, the field exposure were performed to analyze the subcellular distributions of contaminants and adverse effects of chemicals combined with cell-based in vitro assays and in situ tests. Further, the dynamic exchanges, translocation and mobilization of contaminants such as metals were then clarified among the "various particles, pore water and cells in exposed organisms" interfaces of matrix through measuring relevant dynamic parameters and resultant induced fluxes during experimental procedures. Moreover, coupled with chemical analysis to quantify the mitochondrial components (mitochondrial proteins, lipids, and nucleic acids, modulating mitochondrial membrane potential and ATP production et al.,) within culture wells of primary cells and molecular approaches to assess the expression of responsive genes in field exposure, the mechanisms of associated toxicity were elaborated and the interactive relationships were then obtained between chemical bioavailability and in-situ stress. Simultaneously, the assays of cell-based evaluation and monitoring were established considering the consistency of framework as protocols among cell culture, field tests and exposure effects. Overall, the adverse outcomes acquired in this study support full-scale considerations of environmental prevention and retrieval and thus provide robust tool to scientifically extrapolate the environmental quality guidelines (EQGs), further improving accuracy and ecological relevance towards future pollution monitoring as powerful tools and more comprehensive risk assessments in complex scenarios. (The author acknowledges financial support by Grant No. 21777156/B070403 from National Nature Science Foundation of China).

### 375 Identifying genomic networks associated with mitochondrial dysfunction: A meta-analysis approach

*D.A. Dreier, N.D. Denslow, C.J. Martyniuk, University of Florida / Physiological Sciences*

Environmental chemicals can affect mitochondrial function and lead to adverse effects on survival, growth, reproduction, and development in wildlife. Adverse outcome pathways (AOPs) have provided a framework to link mitochondrial dysfunction to apical responses, but further work is needed to establish causality through intermediate key events. Characterizing these key responses are important for AOP construction and required to provide meaningful biomarkers for mitochondrial dysfunction. Thus, the objective of this study was to identify transcriptome networks associated with mitochondrial dysfunction. Briefly, rank order gene lists (ROGLs) were generated for all chemicals in the Comparative Toxicogenomics Database consisting of 5 or more gene interactions for "mRNA:increases^expression" and "mRNA:dereases^expression". We then leveraged high-throughput screening data from the Tox21 program to identify chemicals that decreased the mitochondrial membrane potential. Specifically, chemical records were classified based on hit calls (i.e., active or inactive) in the "TOX21_MMP_ratio_down" assay. Finally, the percent rank of each gene (based on the ROGLs) was compared between active and inactive substances for "mRNA:increases^expression" (11525 genes) and "mRNA:dereases^expression" (10977 genes). It was found that 237 genes were significantly enriched among active compounds for increased mRNA expression, and 152 genes were enriched for decreased mRNA expression ($p < 0.05$). Gene lists were then leveraged in an over-representation enrichment analysis in WebGestalt to identify gene ontologies and functional pathways associated with mitochondrial dysfunction. It was found that biological processes related to lipid metabolism and carboxylic acid metabolism were upregulated, while steroid metabolic processes and responses to hormones were downregulated. Similar results were obtained in a functional pathway analysis; significant Reactome pathways for upregulated transcripts associated with mitochondrial dysfunction were related to lipid metabolism (e.g., beta-oxidation of mitochondrial fatty acid) as well as nuclear receptor regulation and estrogen-dependent gene expression. Thus, the results of this analysis indicate that altered lipid metabolism and endocrine signaling are common responses associated with mitochondrial dysfunction, which may lead to subsequent adverse effects in defined AOPs.

### 376 High-throughput chemical screening of mitochondrial toxicants using zebrafish embryos

*C.L. Souders II, University of Florida / Department of Physiological Sciences; O. Adamovsky, Masaryk University; X. Wang, State Environmental Protection Key Laboratory of Wetland Ecology and Vegetation Restoration / School of Environment / Northeast Normal University, Changchun, Jilin,; D.A. Dreier, N. Ector N.D. Denslow, University of Florida / Physiological Sciences; Y. Zhao, School of Environment/ Northeast Normal Univeristy; C.J. Martyniuk, University of Florida / Physiological Sciences*

Mitochondrial dysfunction is a prevalent molecular event that can result in multiple adverse outcomes. Recently, a novel high throughput method to assess metabolic capacity in fish embryos following exposure to chemicals has been adapted for environmental toxicology. Assessments of oxygen consumption rates using the Seahorse XF(e) 24/96 Extracellular Flux Analyzer (Agilent Technologies) can be used to garner insight into toxicant effects at early stages of development. Here we synthesize the current state of the science using high throughput metabolic profiling in zebrafish embryos, and present considerations for those wishing to adopt high throughput methods for mitochondrial bioenergetics into their research. Chemicals that have been investigated in zebrafish using this metabolic platform include herbicides (e.g. paraquat, diquat), industrial compounds (e.g. benzo-[a]-pyrene, tributyltin), natural products (e.g. quercetin), and anti-bacterial chemicals (i.e. triclosan). Some of these chemicals inhibit mitochondrial endpoints in the µM-mM range, and reduce basal respiration, maximum respiration, and spare capacity. We present a theoretical framework for how one can use mitochondrial performance data in zebrafish to categorize chemicals of concern and prioritize mitochondrial toxicants. Noteworthy is that our studies demonstrate that there can be considerable variation in basal respiration of untreated zebrafish embryos due to clutch-specific effects as well as individual variability, and basal oxygen consumption rates (OCR) can vary on average between 100-300 pmol/min/embryo. We also compare OCR between chorionated and dechorionated embryos, as both models are employed to test chemicals. After 24 hours, dechorionated embryos remain responsive to mitochondrial toxicants, although they show a blunted response to the uncoupling agent carbonylcyanide-4-trifluoromethoxyphenylhydrazone (FCCP); dechorionated embryos are therefore a viable option for investigations into mitochondrial bioenergetics.

We present an adverse outcome pathway framework that incorporates endpoints related to mitochondrial bioenergetics. High throughput bioenergetics assays conducted using whole embryos are expected to support adverse outcome pathways for mitochondrial dysfunction.

**377 Oxidative Stress and Apoptosis in Zebrafish (*Danio rerio*) After Exposure to Fungicides at Environmentally Relevant Concentrations**

*N. Kumar, J. Crago, Texas Tech University / Environmental Toxicology / The Institute of Environmental and Human Health (TIEHH)*

Fungicides are widely used to treat fungal disease in agricultural crops, animals, and humans. Recent studies have shown a significant amount of fungicides in streams, groundwater, and sediments. In the current study, we compared the non-target toxicity of two frequently applied classes of fungicides (azole and strobilurin) using larval zebrafish (*Danio rerio*). The goal of this project was to investigate relative fungicide toxicity using behavioral endpoints and molecular biomarkers associated with their mode of action. Zebrafish embryos were exposed to fungicides (tebuconazole, propiconazole, myclobutanil, azoxystrobin, and pyraclostrobin) at different environmentally relevant concentrations, 10 ng/L, 100 ng/L, 10 ug/L, 100 ug/L and 1 mg/L, starting at 4 h post- fertilization (hpf) to 5 days post fertilization (dpf). Behavior assays were conducted to examine swimming behavior (total distance and velocity) at 5 dpf using Danio Vision®. The stability of fungicides under experimental conditions was conducted and analyzed using LC-MS/MS. mRNA expressions (CYP51, GST, Casp9, p53, and BAX), and enzymatic activities (ROS, Casp3, TBARS) were measured to assess the relative toxicity amongst fungicides. The velocity and distance traveled by zebrafish larvae when exposed to azole fungicides (tebuconazole, propiconazole, and myclobutanil) were not significantly different from the controls. However, in the case of the strobilurin chemical class, there was a significant decrease in the swimming behavior of the fish larvae. The molecular biomarkers indicate that strobilurin fungicides and propiconazole may cause oxidative stress and apoptosis at environmentally relevant concentrations. The results for the mitochondrial dysfunction are forthcoming.

**378 Mitochondrial Dysfunction Contributes to the Persistent Effects of Benzo(a)pyrene Across Multiple Generations: Mechanisms and Consequences**

*J.S. Kozal, R. Trevisan, S. Heissenberger, Duke University / Nicholas School of the Environment; N. Jayasundara, Universiy of Maine / School of Marine Sciences; R.T. Di Giulio, Duke University / Nicholas School of the Environment*

The potential for polycyclic aromatic hydrocarbons (PAHs) to have effects across generations is an emerging concern in environmental health; however, the underlying mechanisms are poorly understood. In the present study, we explore role of mitochondria in the multigenerational toxicity of PAHs. Specifically, we characterize the persistent bioenergetic effects of benzo(a)pyrene (BaP) – a model PAH and known mitochondrial toxicant – in F1 (maternally exposed), F2 (cross-generationally or germline exposed), and F3 (transgenerationally exposed) generations following a chronic maternal (F0) dietary exposure using the model teleost *Danio rerio*. Maternally exposed F1 embryos exhibit reduced mitochondrial DNA integrity, reduced mitochondrial function and efficiency, and impaired antioxidant defense systems during development, largely in the absence of effects in exposed F0 females. Metabolic shifts during development create potential for disease pathologies and reduced organismal fitness later in life. In F1 adults, mitochondrial dysfunction presents in cardiac tissue with reductions in mitochondrial reserve capacity. Maternally BaP exposed F1 fish also exhibit altered behavioral, metabolic, and reproductive phenotypes. PAH-induced changes in mitochondrial function and metabolic plasticity persist in the F2 embryos, manifesting at F0 exposure levels that do not cause significant dysfunction in the F1 generation, with important implications for the persistent effects of pollution in the environment. The ability to adjust metabolism is crucial for organisms to effectively respond to a variety of natural and anthropogenic stressors, suggesting that organisms with alterations in fundamental bioenergetic processes may be more sensitive to secondary stressors. Herein we demonstrate that F2 fish exhibit altered metabolic response to thermal stress, reduced thermal tolerance, and fitness tradeoffs. Cross-generational exposure to BaP potentiates metabolic effects under thermal stress even in the absence of effects at baseline temperature. Current studies are evaluating whether mitochondrial dysfunction persists in transgenerationally exposed F3 fish. Taken together, these data suggest that mitochondrial dysfunction contributes to the multigenerational toxicity of BaP, with important implications for human disease pathologies and organismal ecological fitness.

**379 Long-term effects of early-life mitochondrial toxicity in the context of genetic deficiencies**

*J.N. Meyer, D.F. Mello, C. Bergemann, Duke University / Nicholas School of the Environment; K. Hershberger, I. Ryde, Duke University; A. Luz, NIEHS; T. Leuthner, C. Gonzalez-Hunt, Duke University*

Many environmental pollutants target mitochondria, but the mechanisms by which they act vary, including mitochondrial DNA damage (e.g., benzo[a]pyrene), protein inhibition (e.g., arsenic, rotenone), mitochondrial uncoupling (e.g., pentachlorophenol), and redox cycling (e.g., paraquat). Many chemicals have multiple molecular targets. Furthermore, growing evidence suggests that the toxic effects of certain chemicals on mitochondrial function can be highly persistent. This may be especially true of developmental exposures, since mitochondria undergo biogenesis and major functional changes during early development and cellular differentiation. We found that exposure of first larval stage *Caenorhabditis elegans* to arsenic as well as ultraviolet C radiation (UVC; employed to caused persistent mitochondrial DNA damage) exposure caused lifelong decreases in ATP, while rotenone caused lifelong increases. These exposures also led to significant remodeling of mitochondrial energy metabolism: arsenic caused disruption of pyruvate metabolism and Krebs cycle activity, UVC caused changed in insulin signaling and mitochondrial oxidative stress pathways, while rotenone resulted in activation of the glyoxylate and glycolytic pathways in an apparently compensatory fashion. Mutations in mitochondrial fusion, fission and autophagy genes exacerbate the toxic effects of other environmental agents including arsenic, rotenone, and paraquat, underscoring the importance of these homeostatic pathways in defending against mitochondrial toxicants. We are currently examining the effects of additional mitochondrial toxicants, including pentachlorophenol and pyraclostrobin. We are also testing whether mitotoxicants acting on different molecular targets have common effects on dopaminergic degeneration and activity levels, hypothesized to be common downstream outcomes of mitochondrial dysfunction.

**380 Rotenone-induced mitochondrial dysfunction alters pathogen resistance in Caenorhabditis elegans**

*D.F. Mello, Duke University / Nicholas School of the Environment; L. Perez, C.M. Bergmann, Duke University; C. Shoben, L.R. Baugh, Duke University / Biology; J.N. Meyer, Duke University / Nicholas School of the Environment*

Growing evidence have shown that mitochondrial dysfunction not only compromises the energetic metabolism of cells, but also play key roles in other physiological processes such as immunomodulation. We hypothesize that mitochondrial toxicity can be a common link between increased prevalence in immune-related disorders and toxic environmental exposures. To test this hypothesis, we are using the pesticide rotenone –a widely known mitotoxicant that inhibits complex I– and the model organism *Caenorhabditis elegans*. Worms were dosed twice in liquid since eggs at 0 and 24h to 0.25 and 1 uM Rotenone (Rot) or vehicle (1% DMSO; Ctrl) and harvested at 48h. After a further 48h of detoxification period, worms were used to analyze: body length; oxygen consumption rates (OCR); nuclear (nDNA) and mitochondrial (mtDNA) DNA copy number; and survival rate in *Escherichia coli* strain OP50, *Pseudomonas aeruginosa* strain PA14, and *Salmonella enterica* serovar Typhimurium strain SL1344. Our preliminary results show that Rot-exposed worms presented a dose-dependent decrease in body length, and a decrease in basal, ATP-linked and non-mitochondrial OCR, as well as mitochondrial spare capacity. The mtDNA:nDNA ratio showed a trend to higher levels only in worms treated with Rot 1uM. Interestingly, Rot-exposed worms lived longer than Ctrl animals (13% increase in median survival for both doses), but were more susceptible to PA14 (12% decrease in median survival for both doses). However, worms treated with the highest Rot dose revealed a higher resistance to SL1344 (11% increase in median survival), whereas worms exposed to the lower dose were as susceptible as the Ctrl group. These same analyses were also conducted with the offspring (F1) of the Rot exposed worms (P0), however our preliminary results do not support any heritable effects for the measured phenotypes. Altogether our findings suggest that early life exposure to rotenone can promote later life mitochondrial dysfunction (evidenced by the decreased mitochondrial respiration parameters) and alter the capacity of individuals to fight pathogenic bacteria. Next, we will perform transcriptomic and epigenetic analysis to further understand the mechanisms behind the cross-talk between mitochondrial function and immunocompetence.

**381 Twinkle twinkle little StAR how did things go this far: A case study on the development of an incorrect AOP and the correct AOP**

*S.L. Levine, Monsanto Company / Global Regulatory Sciences*

Mitochondrial effects are frequently over looked as a mechanism of action for an observed effect either in in vitro or in vivo test systems. Often an observed effect *in* in vitro or in vivo studies assays can be related to a nonspecific cytotoxic effect on mitochondrial structure and function. This presentation will provide an informative case study where an adverse outcome pathway (AOP) was incorrectly developed for a specific effect on steroidogenesis rather than for a nonspecific effect to steroidogenesis through an effect on mitochondrial structure and function by a surface-active chemical at supraphysiological concentrations. The original study incorrectly concluded that the surface-active chemical had a direct effect on expression of the Steroidogenic Acute Regulatory (StAR) protein, which is widely considered to be the initial and rate limiting step in steroidogenesis. This presentation will highlight the oversight that was made in the research that developed the original AOP, which subsequently became well-accepted in the literature, and how a rigorous secondary evaluation of mitochondrial structure and function was used to characterize the actual mechanism of action. In addition, the results from this analysis have been placed into an AOP, with disruption the mitochondrial electrochemical gradient as the molecular initiating event, and has been put this effect into the context of an environmental risk assessment.

## Modeling and Data Analysis Tools to Predict the Fate and Transport of Pesticides in the Environment

**382 An integrated RICEWQ-AnnAGNPS modeling system to evaluate the fate and transport of Thiobencarb in Colusa Basin, Northern California**

*R. Wang, UC Davis / Land, Air and Water Resources; R.L. Bingner, USDA-ARS / National Sedimentation Laboratory / Watershed Physical Processes Research Unit; Y. Luo, California Department of Pesticide Regulation; Y. Yuan, USEPA; M.A. Locke, USDA-ARS / National Sedimentation Laboratory / Water Quality and Ecology Research Unit; D.L. Denton, USEPA Region 9 / Water Quality Assessment Section; M. Zhang, UC Davis / Land, Air and Water Resources*

As a pre-emergent or early post-emergent herbicide, thiobencarb is widely used in Northern California rice fields. Released paddy water containing thiobencarb may pose ecological risks to non-targeted organisms living in downstream water bodies. Current watershed models usually lack proper mechanisms to accurately represent the complicated hydrological and water quality conditions in rice fields. Therefore, they are not suitable to capture the fate and transport of thiobencarb in rice fields. In this research, we proposed an integrated modeling system: RICEWQ-AnnAGNPS to correctly reflect the dynamics of thiobencarb at rice fields, as well as the subsequent processes after paddy water is discharged and transported to downstreams. RICEWQ model, which is specifically designed for rice fields, is first setup at all rice paddies in Colusa Basin to simulate paddy water discharge and thiobencarb exposure at the edge of fields. Watershed model, AnnAGNPS is setup in the same region to capture the flow discharge from landuses other than rice. Landscape processes of thiobencarb from fields to reaches and channel routings are also simulated by AnnAGNPS. Consequently, the impact of upstream rice pesticide application on exposures at receiving water bodies can be evaluated, with the implementation of the proposed coupled modeling system in Colusa Basin, Northern California.

**383 Methodology for Prioritizing Pesticides for Surface Water Monitoring in Agricultural and Urban Areas of California**

*Y. Luo, California Department of Pesticide Regulation; X. Deng, California EPA / Surface Water Protection Program; R. Budd, Cal EPA / Dept. of Pesticide Regulation; M. Ensminger, CDPR / Environmental Monitoring*

California Department of Pesticide Regulation (CDPR)'s Surface Water Protection Program is developing a more consistent and transparent modeling approach for the prioritization of pesticides for surface water monitoring in California. A computer model, Surface Water Monitoring Prioritization (SWMP) model, has been developed (http://cdpr.ca.gov/docs/emon/surfwtr/sw_models.htm) with CDPR's Pesticide Use Reporting (PUR) database as the primary input data. Data from USEPA Aquatic Life Benchmarks, IUPAC Pesticide Property Database, and USGS National Hydrography Dataset are also incorporated into the model. The model generates monitoring priority lists for pesticide ingredients and their degradates, and optimizes monitoring project planning by answering the questions: where, when, and what to sample. For consistency with the approach used in agricultural areas, urban PUR data are converted from county scale to watershed scale by considering population density and watershed delineation. This represents one of the first systematic and practical applications of PUR downscaling. Refined analysis on pesticide use data is also incorporated in the recent model improvement for the determination of Areas of Interest (AOI's) and associated Pesticides of Interest (POI's) for monitoring. The model output now provides a short list of HUC12's watersheds (out of the 4,415 HUC12 watersheds in California) and candidate streams to be considered for site selection in a monitoring project.

**384 Time series analysis of pesticide air concentrations--effects of mitigations in selected California agricultural communities**

*F. Sartori, CA Dept of Pesticide Regulation*

The California Department of Pesticide Regulation (CDPR) created the Air Monitoring Network (AMN) to monitor ambient air concentrations of soil fumigants and other pesticides in the three agricultural communities of Ripon, Salinas, and Shafter, California. Time series analysis of AMN air concentrations (2011–2016) for the soil fumigants, methyl bromide (MeBr), methyl isothiocyanate (MITC), and 1,3-dichloropropene (13D), was conducted to assess the effects of federal and state mitigations to reduce pesticide air concentrations. Mitigations directed at reducing pesticide use were broadly classified as use-related factors (UF), whereas those at emission reduction as emission-related factors (EF). The model development methods for intervention analysis also known as Box-Tiao modeling were implemented using SAS PROC ARIMA. Input variables included the corresponding time series of pesticide use, an *ad-hoc* indicator, "season", for the months of peak air concentrations, and intervention indicator variables. "Intervention" was any abrupt change in a time series' mean, variance, or both that was also statistically significant based on the selected ARIMA models. The timing of interventions corresponding to a specific mitigation was either known or unknown. Analyses were performed twice: with non-detects replaced by a constant value of half the laboratory limit of detection (LOD), and by simulated data via maximum likelihood estimation based on the distribution of the values above the LOD. The significance of the use parameter, as well as the autoregressive parameter at lag 12 months, indicated that detections were related to use in a cyclical—mostly annual—pattern for all three fumigants in most locations. The MeBr air concentrations were decreasing overtime with interventions occurring at the end of 2015 in all three locations, supporting evidence that the timing of these interventions coincided with that of both the USEPA UF mitigations and 2015 CDPR EF mitigation. In general, there was a small but significant decrease in MITC concentrations in 2015 for Ripon and Salinas, supporting evidence that both the USEPA and CDPR EF mitigations were effective. For the 13D time series, there were no significant interventions that may be associated with any EF- or UF-type mitigation based on the selected model; and the overall trend remained somewhat constant, likely due a constant 2011–2016 demand in its use to compensate for the decline in MeBr use.

**385 Sorption of phenylurea herbicides by soils: Modelling uncertainty and ruling factors with an artificial neural-based fuzzy inference system**

*B.K. Agbaogun, University of Ibadan / Chemistry; J.M. Alonso, Universidade de Santiago de Compostela / Centro Singular de Investigacion en Tecnoloxias da Informacion (CiTiUS); K. Fischer, University of Trier / Department of Analytical and Ecological Chemistry*

Retention of pesticides by soils is both spatially variable and also one of the most sensitive factors determining losses to surface and groundwater. To date, only a few work has been done to explain this process in tropical soils especially, and generally to uncover the factors that govern the process in both temperate and tropical soils. The purpose of this study was therefore to evaluate the influence of various and interrelated specific soil properties and the pesticide specific molecular descriptors on sorption of pesticides in tropical soils, and to develop and test a simple explainable sorption model. The sorption behavior of five representatives of the phenylurea family (PUH) were studied in twelve soils of contrasting characteristics, stemming from the Southwestern Nigeria. Sorption isotherms and coefficients were obtained by equilibrating the soil samples with 0.01M $CaCl_2$ solutions spiked with increasing concentrations of the target PUHs. HPLC-DAD was used to quantify the target PUHs in solutions at equilibrium. The isotherm data were fitted to Freundlich and linear distribution equations ($R^2 \geq 0.96$ and $R^2 \geq 0.76$, respectively) to obtain the isotherm and distribution coefficients ($K_f$, and $K_d$). Spearman rank correlation was used to determine the specific soil and PUHs properties that have significantly high correlations with $K_f$ or $K_d$. Significant correlations were established between $K_d$ or $K_f$ and the following factors: soil properties (pH, cation exchange capacity, organic carbon, extractable Fe and Mn content, and mass proportions of clay and silt), and the pesticide molecular descriptors [molecular weight ($M_w$) and hydrophobicity index ($logK_{ow}$)]. These were used alongside with PUHs concentrations as potential descriptors. However, due to the problem of multicollinearity between these predictors, multiple linear regression and other similar statistical approach were inadequate to elaborate a model, hence the use of an artificial neural-based fuzzy inference system (ANFIS). Several models of different combinations of the factors were then elaborated under 10-fold cross-validation. Furthermore we carried out a sensitivity analysis of the factors to establish the most important predictor. In conclusion, we successfully used ANFIS to construct a holistic 4 factor system that could model the sorption of PUHs in tropical soils. The model should assist in understanding the fate of pesticides, and for their risk assessment in tropical soils.

**386 Evaluation of Climate Change Effects on Natural Sediment Recovery in an Alpine Lake**

*K. Scheu, Integral Consulting Inc / Marine Science and Engineering; C. Flanary, K. Raghukumar, C. Jones, Integral Consulting Inc; L. Ziliani, B. Groppelli, S. Ceccon, Ramboll Italy; D. Bocchiola, Politecnico di Milano*

Assessing the role of climate change on sediment and contaminant fate and transport is of increasing importance in remedial investigations to accurately evaluate time scales over which recovery can be expected in natural environments. To this effect, the authors undertook a detailed modeling study, validated by field measurements, which examined the role of climate change on sediment fate and transport in an alpine lake in Northern Italy (Lago Maggiore, Italy). The transport of sediment and sediment-bound contaminants throughout Lago Maggiore is important to evaluating and managing long-term environmental risks. As a part of the investigation of sediment dynamics in Pallanza Bay (an embayment of Lago Maggiore, fed by the Toce River), a modeling study was conducted to better understand hydrodynamic processes and the stability of sediment and contaminants, DDT in particular. Sediment dynamics in Lago Maggiore were investigated under two climate change scenarios, as delivered by the Intergovernmental Panel on Climate Change. The two climate models EC-EARTH and ECHAM6 under the Representative Concentration Pathways (RCPs) 8.5, were applied to a previously calibrated and validated hydrodynamic and sediment transport model of Lago Maggiore. These scenarios provided the maximum and minimum river flow and sediment load conditions to the lake, respectively. The predicted deposited sediment was characterized in terms of cumulative thickness, annual average deposition rate, and spatio-temporal distribution trends over a 34 year period (2016-2050). Results of the climate change scenarios indicate that the EC-EARTH RCP 8.5 scenario (with higher flow rates and sediment loading) resulted in higher sediment deposition outside of the river mouth and transported sediment further into Pallanza Bay, similar to the deposition pattern measured by geochronology cores. The ECHAM6 RCP 8.5 scenario with lower flow rates and sediment loading predicted lower sediment deposition near the river mouth and less sediment transport into Pallanza Bay. The predicted sediment deposition rates for ECHAM6 throughout Pallanza Bay were in good agreement with the model hindcast data and historical measurements. The proposed climate change scenarios provide an assessment of potential future deposition patterns that are reasonable under the expected evolution of climate change within the next half century.

**387 The Pesticide Emission Model (PEM): A tool for assessing pesticide volatilization from agricultural applications**

*S. Ghosh, K. Crist, Ohio University / Chemical & Biomolecular Engineering; S. Grant, Syngenta Crop Protection LLC*

Predicting the atmospheric fate and transport of pesticides is complex and challenging due to the compounding factors of the localized environment (e.g. environmental conditions, crop, topography) and physical properties of the pesticide. The current work introduces the development of the Pesticide Emission Model (PEM), a deterministic model that predicts diurnal volatilization emission flux rates after agricultural spray applications to soil and plant surfaces. The PEM utilizes dynamic transport processes, fate mechanisms, physicochemical properties and environmental conditions (e.g. temperature, wind speed, solar radiation, precipitation, land cover, leaf area index (LAI), etc.) to determine mass transfer rates from the sprayed surface to the atmosphere. Validation of the PEM model shows strong agreement with hourly observations of soil and plant volatilization. A user interface was also developed to position PEM in a more user-friendly platform. This interface couples the modeled emission/volatilization rates with AERSCREEN and AERMOD dispersion models to assess off-target deposition and air concentrations; thereby, informing risk assessments by providing greater insight about potential off-target exposure of pesticides.

**388 AGDISP: Canopy Interactions and Future Development**

*H. Thistle, USDA Forest Service / FHAAST Forest Health Protection*

The AGDISP computer model is used to estimate pesticide deposition from various application scenarios. The model code is dynamic and the research version undergoes changes regularly. The nature of this model and other deposition models will be discussed as well as future model development directions. Recently, two forest deposition data sets became available to test against AGDISP predictions. Both scenarios require physics that either are not in AGDISP or are treated in an extremely simplistic manner. One data set is of in-canopy deposition in a deep coniferous canopy and one data set shows deposition in rowed trees in a young conifer plantation (this geometry violates the continuous canopy assumption in AGDISP). The experimental data is discussed, how these types of data sets are used to improve AGDISP is described and potential approaches to improve the model physics are presented.

**389 Towards Improved Modeling of Pesticide Volatilization: Using Measured Soil-Air Partition Coefficients in a Pesticide Volatilization Model**

*S. Das, University of Otago / Chemistry; K.J. Hageman, Utah State University / Department of Chemistry and Biochemistry*

Volatilization can cause significant loss of pesticides from agricultural fields, leading to reduced efficacy of the pesticide and harm to non-target ecosystems. Our research group previously developed a model to predict the cumulative volatilization losses of pesticides from agricultural fields, based on environmentally relevant partition coefficients and the mass-balance distribution of pesticides between soil, air, and water compartments. Originally, we used $K_{soil\text{-}air}$ partition coefficients for pure active ingredients input values in the model. However, to better understand and predict pesticide volatilization, we need to know how partition coefficients are affected by the chemicals (e.g. solvents, wetting agents, solvents, dyes and/or other adjuvants) found in real commercial pesticide formulations. In addition, surfactants designed to decrease pesticide volatilization are sometimes added separately to spray tanks, but little actual data about their effects on pesticide volatilization exist in the literature. In this project, a modified version of a fugacity meter was used to measure the $K_{soil\text{-}air}$ values of three semi-volatile pesticides (trifluralin, chlorpyrifos & pyrimethanil) (a) as pure active ingredients, (b) in a typical commercial formulation, and (c) in the presence of active ingredient or commercial formulation with additional surfactant, Synoil™, which is sold to enhance pesticide uptake and spreading. Experiments were conducted at several environmentally relevant temperatures (10-30 °C). We found that the $K_{soil\text{-}air}$ values in commercial formulations (i.e. $K_{soil\text{-}air,\ formulation}$) were more than 10 times lower than those for pure active ingredients. For example, the log $K_{soil\text{-}air}$ for pure pyrimethanil was 8.44 whereas that for pyrimethanil in its commercial formulation was 7.28. However, commercial surfactant Synoil™ had minimal effect on $K_{soil\text{-}air}$ values. When the $K_{soil\text{-}air,\ formulation}$ values were used as input values in the pesticides volatilization model, the cumulative percentage volatilization for 24 hours increased by up to five times compared to when using the $K_{soil\text{-}air}$ value for the active ingredient alone. This suggests that a better qualitative understanding of how adjuvants and surfactants affect pesticide-soil interaction is needed.

## Fate and Effects of Metals – Regulatory and Risk Assessment Perspective

**390 Multiple Linear Regression Models for Developing Bioavailability-adjusted Freshwater Criteria for Lead**

*D.K. DeForest, L.M. Tear, Windward Environmental LLC; M.J. Chowdhury, International Lead Association; K. Brix, EcoTox / Marine Biology and Ecology*

Metals bioavailability and toxicity may be predicted using mechanistic approaches, such as the biotic ligand model (BLM), and empirical approaches, such as multiple linear regression (MLR). BLMs for lead (Pb) in freshwater have been developed and used to propose bioavailability-based ambient water quality criteria and threshold effect concentrations in the United States and Europe. For regulatory applications in the United States, interest is developing in using empirical approaches that consider the influence of multiple water chemistry parameters on metals bioavailability (such as dissolved organic carbon [DOC], pH, and hardness). The U.S. Environmental Protection Agency (USEPA), for example, recently recommended draft MLR-based aquatic life criteria for aluminum. In the present evaluation, we developed MLR-based models for Pb and three forms of aquatic life (algae, invertebrates, and fish). In general, Pb MLR models were able to predict toxicity with a level of accuracy that is comparable to the BLM. The Pb MLR models were then used to derive potential acute and chronic MLR-based Pb criteria following current USEPA guidelines for criteria development, as well as using alternative approaches (such as inclusion of algae in the genus sensitivity distribution). Lead MLR models and BLMs, and potential criteria using each, will be compared and assessed.

**391 Development of the Draft Canadian Water Quality Guidelines and Ecological Screening Assessment for Manganese Using a New Statistical Approach**

*R.L. Dalton; K. McTavish, T. El-Fityani, Environment and Climate Change Canada; D.J. Spry, Environment and Climate Change Canada / Water Policy & Coordination Direct*

Manganese (Mn) is a naturally-occurring and abundant metal, as well as an essential trace element. Globally, manganese is the fourth most widely used metal after iron, aluminum and copper. Manganese is widely used as an additive and element in the production of steel and other alloys, as a component of dry-cell alkaline batteries, and in a wide range of other products. Manganese enters the environment from geological weathering, as well as from point sources from a variety of industrial sectors including: pulp and paper, wastewater and sewage treatment, metal ore and coal mining, and bitumen extraction. As part of the current phase of the Chemicals Management Plan (CMP), Environment and Climate Change Canada and Health Canada are assessing the potential for manganese to cause harm to the environment and to human health under the Canadian Environmental Protection Act, 1999. Concurrently, draft Canadian Water Quality Guidelines (CWQG) for the protection of freshwater aquatic life for manganese are being developed through the Canadian Council of Ministers of the Environment (CCME). The draft long-term guideline values incorporate the bioavailability and toxicity modifying factors pH and hardness. The draft CWQG for manganese incorporates a new statistical method that fits species sensitivity distributions using maximum likelihood estimation coupled with a model averaging approach. For a given pH and hardness, the 5th percentile of the model weighted-average species sensitivity distribution becomes the long-term CWQG and the predicted no effect concentration (PNEC). The advantages of this new approach will be discussed, as well as how the approach will be used in the CMP draft ecological screening assessment for manganese and its compounds.

**392 Update on the 2018 Aluminum Ambient Water Aquatic Life Criteria**

*D.M. Eignor, K. Gallagher, USEPA / Office of Water*

The US Environmental Protection Agency (EPA) is updating its 1988 recommended aquatic life criteria for aluminum under Clean Water Act Section 304(a). The 1988 criteria account for the influence of pH on toxicity, similarity of acute toxicity of fish and invertebrates, and the greater sensitivity of invertebrates in chronic toxicity tests. The 1988 document recommended an acute criterion of 750 µg/L and a chronic criterion of 87 µg/L when the pH is between 6.5 and 9.0. The effects of hardness and dissolved organic carbon (DOC) were not considered in the 1988 criteria derivation. Over the past 25 years, new acute and chronic toxicity data for both freshwater and saltwater organisms have been published. Additional toxicity data for the eight recommended families as well as mussel toxicity studies are included in the new evaluation. EPA compared several approaches that reflect water quality condition impacts on toxicity including complete and simplified aluminum Biotic Ligand Models (BLMs) and multi-linear regression equations using pH, hardness, and DOC parameters. Comparisons were conducted to facilitate evaluation of the various approaches for criteria development. The multi-linear regression approach using pH, hardness, and DOC parameters was selected for criteria development based on the work of DeForest *et al.* 2018. This approach was selected due to 1) the transparency of the model, 2) the similarity and accuracy of the results relative to the available BLM model outputs and empirical data, and 3) the decreased number of input water chemistry data needed to derive criteria at different sites, which increases utility of the model for end-users.

**393 Models, beakers, and ecosystems: Utilizing linked biotic ligand and biodynamic models to predict accumulation in field collected invertebrates.**

*T.S. Schmidt, USGS / Colorado Water Science Center; C.A. Mebane, USGS / Idaho Water Science Center; L.S. Balistrieri, USGS / School of Oceanography; J. Miller, USGS / Fort Collins Science Center*

Models predictive of metal accumulation and effects generally fall into two types of models, biodynamic- and biotic ligand-style models. Each comes with advantages and disadvantages. Biodynamic models account for species-specific process that control metal accumulation under simplified lab scenarios but have limited utility to ecosystem management because they are difficult to extrapolate to food webs and rarely predict effects on organisms. Biotic ligand models predict the lethality of metals due to differences in water quality on metal speciation. These models are more easily extrapolated to ecosystems but they do not account for the biological processes known to control metal accumulation. To improve the prediction of metal accumulation and effects to ecosystems we developed a linked biotic ligand-biodynamic modeling framework. To do so we first developed a framework using mesocosm data of single and metal mixture accumulations into periphyton and the aquatic insect *Brachycentrus americanus.* We then used this model to predict metal accumulation into field mayflies and caddisflies. Model predictions suggest while more than 80 percent of the metal accumulated into insects (mesocosm or field) was acquired via the diet; bioavailability of metals to periphyton was described by solution chemistry. The metals accumulation was in turn predictive of adverse effects to communities. We utilized advantageous aspects of both modeling paradigms and thus made strides at developing a model of metal accumulation into food webs that could be applied to the management of ecosystems.

**394 Long-term effects of metal-contaminated sediments from streams in the Tri-State Mining District on juvenile freshwater mussels**

*J.M. Besser, J.L. Kunz, C.D. Ivey, D. Cleveland, J.A. Steevens, USGS / Columbia Environmental Research Center*

Field studies have documented that the abundance and diversity of freshwater mussels were reduced in metal-contaminated streams that drain the Tri-State Mining District (TSMD) of Missouri, Kansas, and Oklahoma. However, previous laboratory toxicity studies found that juvenile mussels were not among the most sensitive benthic taxa in short-term (4-week) toxicity tests with TSMD sediments. In the present study, we conducted longer-term (12-week) toxicity tests with the fatmucket mussel (*Lampsilis siliquoidea*)and a commonly tested amphipod(*Hyalella azteca)* to establish site-specific thresholds to protect freshwater mussels of the TSMD from injury by toxic metals. Fine streambed sediments (< 2 mm) were collected from depositional areas adjacent to 24 study sites that selected for a concurrent mussel community survey. Sediment toxicity was determined using standard 6-week amphipod tests and using a new protocol for conducting 12-week sediment exposures with juvenile mussels. Both tests included regular replacement of overlying water to maintain water quality conditions similar to TSMD stream waters. In the mussel test, sediments were replaced every four weeks to avoid fouling by food or waste and to allow monitoring of mussel survival and growth (by photography) at each four-week interval. Toxicity thresholds (expressed in terms of sediment zinc or the zinc-lead-cadmium mixture) from the 42-day amphipod tests and 12-week mussel tests were lower than those from previous 28-day tests with these species. Toxicity thresholds for mussels in 12-week tests were 80-90% lower than threshold for previous 4-week tests and were equal to or lower than thresholds from 6-week amphipod tests. These results support our hypothesis that previous short-term sediment toxicity tests substantially underestimated long-term effects of zinc and associated metals on mussels. We are currently investigating whether concurrent exposure of mussel to metal mixtures in stream water result in even lower effective thresholds for toxicity of metals in sediment, and whether lower toxicity thresholds for sediment metals will better predict adverse effects on mussel communities in the TSMD streams.

**395 A Leach Rate Cap on Copper Antifouling Paints in California: A Regulatory Case Study**

*A. Burant, California Department of Pesticide Regulation / Surface Water Protection Program; X. Zhang, California Department of Pesticide Regulation / Environmental Monitoring; N. Singhasemanon, California Department of Pesticide Regulation*

Copper is used as a biocide in boat hull coatings to prevent the biofouling of aquatic vessels. Copper antifouling paints (Cu-AFPs) are the most commonly used biocides in California marinas. A monitoring study by the California Department of Pesticide Regulation (CDPR) found that large saltwater marinas in Southern California typically have the highest dissolved copper (DCu) concentrations. Recreational boat marinas are particularly susceptible to pollution from Cu-AFPs because they are designed to be poorly flushed and are densely packed with seldom-used recreational vessels that have Cu-AFPs applied to their hulls. The monitoring study found that measured concentrations of DCu routinely exceeded national ambient water quality criteria for the protection of aquatic life (i.e., above the chronic and/or acute water quality criterion of 3.1 and 4.8 µg/L, respectively) in many California saltwater marinas. CDPR also measured toxicity in 47 marina samples, eight of which displayed statistically significant toxicity and used the freshwater and saltwater Biotic Ligand Model (BLM) to predict toxicity for the remaining samples. The saltwater BLM predicted toxicity in 18% of the samples. In response to the water quality exceedances and associated toxicity, CDPR developed and employed regulatory mitigation strategies to reduce DCu in marina waters. These efforts were focused on determining a leach rate cap for Cu-AFPs. The cap was developed with aid of the Marine Antifoulant Model to Predict Environmental Concentrations (MAMPEC), which is an integrated two-dimensional hydrodynamic and chemical fate model. Five marina scenarios, ranging in marina dimensions and number of boats, were modeled to determine leach rates necessary to achieve DCu concentrations less than the chronic water quality criteria. Hull cleaning, a major contributor to DCu in marinas, was also incorporated. The selected leach rate of 9.5 µg/cm$^2$/day was based on both risk assessment and pest management efficacy requirements.

**396 Do Constructed Wetlands Remove Metals or Increase Metal Bioavailability?**

*X. Xu, University of Georgia; G.L. Mills, University of Georgia / Savannah River Ecology Laboratory*

The H-02 wetland was constructed to treat building process water and storm runoff water from the Tritium Processing Facility on the Savannah River Site (Aiken, SC). Monthly monitoring of copper (Cu) and zinc (Zn) concentrations and water quality parameters in surface waters continued from 2014 to 2016. Metal speciation was modeled at each sampling occasion. Total Cu and Zn concentrations released to the effluent stream were below the NPDES limit, and the average removal efficiency was 65.9% for Cu and 71.1% for Zn. The metal-removal processes were found out to be seasonally regulated by sulfur cycling indicated by laboratory and model results. High temperature, adequate labile organic matters, and anaerobic conditions during the warm months (February to August) favored sulfate reduction that produced sulfide minerals to completely remove metals. However, the dominant reaction in sulfur cycling shifted to sulfide oxidation during the cool months (September to next March). High concentrations of metal-organic complexes were observed, especially colloidal complexes of metal and fulvic acid (FA), demonstrating adsorption to organic matters became the primary process for metal removal. Meanwhile, the accumulation of metal-FA complexes in the wetland system will cause negative effects to the surrounding environment as they are biologically reactive, highly bioavailable, and can be easily taken up and transferred to ecosystems by trophic exchange.

### 397 Controlled Field Exposures Suggest Modes of Arsenic Accumulation in Adult Eastern Softshell Clams

*K. Kerns, US Army Corps of Engineers; M. Michalsen, US Army Engineer Research Development Center / Environmental Engineering & Technology Section; G.R. Lotufo, US Army Corps of Engineers / ERDC; K. Adams, USEPA; B. Duncan, USEPA / Region 10; E. Hale, USEPA; B. Gardiner, US Army Corps Engineers / Engineering and Technology*

Subsistence and recreational shellfish consumption is an important exposure pathway in evaluating human health risks associated with contaminated sediments in the Pacific Northwest. Both natural and anthroprogenic sources of arsenic have led to elevated concentrations in both sediments and shellfish in Puget Sound and is an important contaminant to consider when pursing remedial activities at contaminated sediment sites. Understanding how and from which media shellfish bioaccumulate arsenic is critical to making science-based decisions on whether and how to remediate arsenic contaminated sediments. The purpose of this field study was to understand the uptake of organic and inorganic arsenic from bedded sediments by Eastern softshell clam (Mya arenaria), including understanding the distribution of arsenic in different tissues and the potential for iron amendments to reduce arsenic bioaccumulation. In situ exposures were conducted in two plots located on the west bank of the Lower Duwamish Waterway Superfund Site, Seattle, Washington. Sediment concentrations in these two plots were 30 mg/kg and 10 mg/kg total arsenic. Sediment treatments included homogenized sediment, undisturbed (or non-homogenized) sediment, clean sand, and homogenized sediment with an iron-amendment. Sediment exposures were conducted in six bottomless, perforated 5 gallon buckets that were inserted into the intertidal substrate, allowing for replicated, controlled sediment conditions with freely draining tidal pumping and porewater exchange through the sediment. Six to eight clams were planted in each exposure chamber and exposed for approximately 120 days prior to collection. Results of this study show that bedded sediment had an overwhelming influence on the total body burden of arsenic in clams. Tissue concentrations in the high arsenic treatment were significantly greater than those of the low concentration plot and sand treatment, indicating that the influence of overlying water was limited. Arsenic was found to preferentially accumulate in the siphon skin of clams, with inorganic arsenic concentrations in the siphon skin approximately three orders of magnitude greater compared to the main body. This result corroborates with similar findings published by Oregon DEQ and allows for the management of human-health risk at the site. Iron amendment also shows promise, with decreased tissue concentrations of both total and inorganic arsenic for clams exposed to iron amended sediment.

## Remediation and Restoration: Assessing and Measuring Effectiveness for Contaminated Sediments

### 398 The Pros and Cons of Performance-Based Site Remediation

*G.I. Greenberg, T.A. Verslycke, Gradient*

The goal of hazardous waste site remediation is to reduce unacceptable risks to human and ecological populations potentially exposed to site contamination. Risks to exposed populations are quantified in human health and ecological risk assessments, which serve as the basis for potential risk management actions when unacceptable risks are found. Risk management actions can include removal, engineering controls, and/or site use restrictions *(e.g.*, administrative controls) to reduce or eliminate exposures that were estimated to result in unacceptable risks. To inform remedial extent, preliminary remediation goals (PRGs) are typically calculated assuming a target risk level and relying on the information compiled in the risk assessments. These PRGs are then used as delineation criteria during remediation. In a performance-based remediation, remedial extent is determined in an iterative manner by modeling post-remediation exposures and risks for different remediation scenarios. This allows for the selection of a defined remedial footprint and does not require PRGs or confirmatory sampling in some cases. A performance-based remediation approach can be an effective tool to quantitatively evaluate the estimated benefit (*i.e*., risk reduction) of different remediation option. This approach can also be used to more easily communicate the quantitative impact of key uncertainties identified in the risk assessments on different remediation options. This allows risk managers to select a remedy that is protective of the most sensitive receptors identified in the risk assessment with an understanding of the potential diminishing benefits and increasing uncertainties associated with more extensive remediaton. The pros and cons of a performance-based approach, as compared to a traditional approach, will be illustrated using a project example where soil remediation was warranted due to unacceptable risks from metals in soil to insectivorous mammals and birds. A performance-based approach was used at this site to facilitate communication between the responsible party and the risk manager on selecting the appropriate extent of remediation and circumvent the need for agreement on PRGs and post-confirmatory sampling.

### 399 Is Too Much Wood a Bad Thing? Using Wood Waste Guidance to Improve the Cleanup of Port Gamble Bay

*R. McMillan, J. Evered, L. Machut, WA State Department of Ecology / Toxics Cleanup Program*

Washington’s Toxic Cleanup Program (Department of Ecology) is tasked, in part, with regulating remediation resulting from historic industrial activities. This includes addressing contamination from historic sawmills and wood products manufacturing that occurred throughout Puget Sound over the past 100 years. Wood waste has been a major driver in numerous large scale, nearshore cleanups in Washington State, where its presence contributed substantially to the footprint of the active cleanup and the volumes of sediment requiring remediation. However, cleaning up wood waste is costly and time consuming. Also, the nature of wood waste is highly variable which makes its toxic effects difficult to predict. Unlike many traditional contaminants, there is rarely a simple metric that accurately characterizes effects. A recent cleanup in Port Gamble Bay will be used as a case study to show how the state’s Sediment Management Standards and Wood Waste Guidance can be used to develop a weight of evidence approach, using physical surveys, numeric chemical criteria, and bioassays, to identify areas requiring remediation from overlapping wood waste, PAH, and dioxin contamination.

### 400 Designing and implementing a remedy effectiveness assessment for Thomson and Scanlon Reservoirs in the St. Louis River AOC

*M. Mills, USEPA / National Risk Management Research Laboratory; T.P. Luxton, USEPA / Land and Materials Management Division; J.M. Lazorchak, USEPA / Office of Research and Development; K. Fritz, J. Hoffman, USEPA / ORD / NHEERL; L.P. Burkhard, USEPA / ORD / NHEERL / Mid-Continent Ecology Division; G. Peterson, USEPA / ORD / Duluth; G. Hanson, USEPA / ORD / NHEERL / Mid-Continent Ecology Division/ Duluth, MN; M. Kern, USEPA / GLNPO; D. Walters, USGS / Fort Collins Science Center; M. Elliott, Minnesota Pollution Control Agency*

The Great Lakes National Program Office (GLNPO) and the Minnesota Pollution Control Agency (MPCA) are developing remediation and restoration actions for the Thomson and Scanlon Reservoirs on the St Louis River. A multi-Agency team of researchers and project managers from EPA ORD, EPA GLNPO, MPCA, and USGS conducted baseline assessments along multiple lines of evidence using physical, chemical, and biological methods and metrics. The team designed and executed the baseline characterization from 2016-2017 focused on characterizing the two reservoirs for the primary contaminants of concern (COCs) dioxins/furans and mercury. Innovative measures and metrics were used to assess the COCs impacts in the reservoir systems. These included biological metrics such as various macrobenthos measures, spiders, swallows, and multiple fish species. Chemical metrics included surface sediment, sediment at discrete depths, passive samplers, and water measurements of the COCs. Finally, physical measures included bathymetric surveys and sediment physical characterization. The results of these assessments will be presented and compared to a reference condition.

**401 Influence of remediation on sediment toxicity within the Grand Calumet River, Indiana**

*J.A. Steevens, J.M. Besser, R.A. Dorman, USGS / Columbia Environmental Research Center; D.W. Sparks, US Fish & Wildlife Service / Indiana Ecological Services Field Office*

The Grand Calumet River (GCR), located in northern Indiana, is contaminated due to a wide range of historical industrial activities. This study was conducted to determine the influence of sediment remediation within the GCR on the levels of sediment contaminants and toxicity to sediment dwelling organisms. Sediments with high concentrations of metals and organic compounds were remediated through a combination of removal, capping, and activated carbon amendments between 2005 and 2016. A combination of acute and chronic sediment toxicity tests were conducted three times from 2013 to 2017 using the amphipod *Hyalella azteca*, the midge *Chironomus dilutus*, and the mussel *Lampsilis siliquoidea*, in sediments from 29 sites, including both remediated and non-remediated sites. Previous studies focused on short-term (10-d) exposures to evaluate the severity of sediment contamination at the site, with results of longer-term (28- to 42-d) exposures conducted to determine if sediments with lower concentrations of contaminants after remediation were still toxic. Reduction in survival and biomass was observed for all sediments across the GC although the level of toxicity varied from year-to-year. The chemistry and bioassay lines-of-evidence were evaluated using a scoring approach and evaluated across three regions of remediated sites and compared to non-remediated locations. Toxicity data for each year and sample location was scored based on the number of toxicity endpoints that were significantly reduced relative to the control. Temporal trends in toxicity scores, such as such as year-to-year variation, indicate there is a wide range of toxicity in both remediated and non-remediated sites that may be due to other site-specific factors associated with the site. Site specific factors such as recontamination due to combined sewer outfalls and other sources will be discussed as potential conditions affecting remedy success and long term stability.

**402 PCB export at the lower Ottawa River (Maumee River AOC): An analysis of sediment, passive samplers, aquatic invertebrates, and riparian spiders**

*R.R. Otter, Middle Tennessee State University / Biology; D. Walters, USGS / Fort Collins Science Center; J.M. Lazorchak, USEPA / Office of Research and Development; K. Fritz, USEPA / ORD / NHEERL; M. Mills, USEPA / National Risk Management Research Laboratory*

Environmental dredging at select site locations was performed within the lower Ottawa River, a portion of the Maumee River Area of Concern (Ohio, USA), in 2010 to remediate sediments contaminated with PCBs, PAHs, and lead. Prior to dredging, we designed a multi-metric study to assess contaminant fate and transport, ecosystem response, and recovery using a multiple lines of evidence approach. We measured PCB concentrations in surface sediment, passive samplers deployed in the water column, aquatic invertebrates, and spiders from 2009-2013 & 2015. Site-specific PCB concentrations were significantly and positively correlated among all metrics across all years except for sediment. Sediment concentrations at remediated and non-remediated sites were highly variable throughout the study period and were unreliable indicators of PCB concentrations in biota. PCB concentrations in aquatic invertebrates were highly correlated with concentrations measured in passive samplers, and in turn, were strongly predictive of concentrations in riparian spiders that are specialized predators of adult aquatic insects. All of these measures of PCB uptake, accumulation, and trophic transfer declined by 2015, indicating that the dredging remedy was successful in reducing PCBs concentrations in biota within the Area of Concern.

**403 An Independent Evaluation of the Hudson River PCB Dredging Program**

*K.J. Farley, Manhattan College / Civil and Environmental Engineering; J.E. Baker, University of Washington / Center for Urban Waters; W.F. Bohlen, University of Connecticut; W.R. Geyer, Woods Hole Oceanographic Institution / Applied Ocean Physics and Engineering; S. Litten, Simon Litten; D.K. Ralston, Woods Hole Oceanographic Institution / Applied Ocean Physics and Engineering*

In February 2002, the General Electric Company (GE) was ordered by the U.S. Environmental Protection Agency (EPA) to conduct targeted dredging of PCB-contaminated sediment in a 40-mile stretch of the Upper Hudson River between Fort Edward and Waterford, NY. GE performed dredging of the Upper Hudson in two phases, beginning in May 2009 and ending in October 2015. Following completion of dredging operations, the Hudson River Foundation convened an expert panel to evaluate the effectiveness of the dredging program on the Upper and Lower Hudson. Based on water column and fish monitoring data (through December 2016) and simple model calculations, the panel concluded: (i) the dredging program met mass removal targets for PCB-contaminated sediments, (ii) the dredging program was effective in reducing PCB concentrations in fish from Thompson Island Pool, (iii) post-dredging PCB concentrations in fish downstream of Thompson Island Pool showed mixed results, (iv) the reduction in Tri+ PCB loads to the Lower Hudson during the 2016 post-dredging period were in part due to below-average flows in the river, (v) water column, sediment and fish in the Lower Hudson below Albany are showing slow responses to the Upper Hudson dredging program due to the complexities of sediment transport in the Lower Hudson, and (vi) additional years of natural attenuation will be required to reduce PCB concentrations in fish throughout the Upper and Lower Hudson to acceptable levels. Modifications to the post-dredging monitoring program and continued evaluation of the next few years of monitoring data are therefore recommended to assess if natural attenuation will be sufficient in reducing PCB concentrations in fish in a reasonable time frame or if additional remedial actions will be required. The panel's evaluation is currently being extended to include 2017 monitoring data, which corresponds to the second year of the post-dredging period.

**404 Retrospective Review of Long-Term Biological Metrics to Assess Completed Sediment Cleanup Remedy Effectiveness**

*C.R. Patmont, J.P. Connolly, Anchor QEA, LLC*

Contaminated sediments pose unique challenges, both technically and administratively. Throughout North America, governmental agencies and responsible parties have been investigating, evaluating, and remediating contaminated sites since the early 1980s under a range of regulatory frameworks. Although the objective of sediment remediation is to reduce potential risks to human health and the environment, unfortunately it is still not clear whether the engineering approaches in most widespread use effectively reduce such risks. Even today, the scientific and engineering community seeks effective approaches to manage contaminated sediment risks. The high costs associated with sediment remediation, coupled with uncertain risk reduction outcomes, have led many practitioners to redouble efforts to collect, learn from, and incorporate new information to improve the effectiveness of remedial operations. Using long-term contaminant bioaccumulation and histopathology monitoring records available for indicator fish species along with other available biological metrics, a retrospective review of the effectiveness of completed large-scale sediment cleanup remedies in the U.S. was initiated. Results of the review to date reveal that the effectiveness of sediment remediation depends in large part on whether surface sediment concentrations are attributable to legacy inputs or the result of ongoing sources. Where ongoing sources control surface sediment concentrations, active remediation of sediments in the absence of additional source control has been ineffective. In these cases, source control has been shown to be effective in accelerating natural recovery of biological metrics. Moreover, exposure control to achieve desired fish tissue recovery has been principally achieved by capping or backfill regardless of whether environmental dredging was undertaken. Ongoing remedy effectiveness evaluations will be summarized.

**405 Assessment of Human Health Benefits and Risks of Contaminated Sediment Remediation**

*J. Kvasnicka, University of Toronto / Earth Sciences Dept; G. Burton, University of Michigan / School for Environment and Sustainability; K. Stylianou, University of Michigan / School of Public Health / Environmental Health Sciences; L. Huang, University of Michigan / Dept of Environmental Health Sciences; J. Semrau, University of Michigan / Civil and Environmental Engineering and Program in the Environment; O. Jolliet, University of Michigan*

Billions of dollars have been spent on environmental dredging projects to remediate contaminated sediments, with billions more slated for this; however, the extent to which this remedy can reduce human health risks needs to be quantified on a population scale and compared with potential induced risks. This study is the first to do so, focusing on the Hudson River Polychlorinated Biphenyls (PCBs) Superfund Site remediation (2009-2015). By utilizing a combination of mechanistic modelling, monitoring, and survey data, we quantify and compare the potentially avoided and induced population health burden of this major dredging project in terms of disability-adjusted life years (DALY) with approximate 95% confidence intervals (CI). The specific aims were as follows: 1) Assess the potential cancer and non-cancer health burden on recreational anglers for a No Action scenario due to bioaccumulation of PCBs in Hudson River fish and exposure through fish consumption. 2) Determine and compare long-term reductions in health burden from reduced fish tissue PCB concentrations under different remedial alternatives, including resuspension, relative to No Action. 3) Investigate the potential health burden induced by the selected dredging remedy from increased air emissions of PCBs, $PM_{2.5}$, and $NO_x$, and fatal occupational incidents. 4) Compare the avoided burden (benefits) with the induced burden (risks). For the No Action scenario, the central estimate health burden attributable to bioaccumulation of PCBs in Hudson River fish and exposure through fish consumption is 11 DALY. Implementing a source control action under Monitored Natural Attenuation (MNA) achieves an avoided burden of 4 DALY (CI 0.06 to 321 DALY) over No Action, while dredging achieves an additional 1 DALY (CI 0.02 to 102 DALY) of avoided burden. The estimated total burden induced by dredging is 40 DALY (CI 7 to 148 DALY), which is dominated by rail transport of PCB waste across the US (25 DALY, CI 4 to 153 DALY), and fatal occupational incidents (14 DALY, CI 0 to 88 DALY). Future decisions on the need for removing contaminated sediments should thus better weigh health risks associated with dredging activities.

## Developments in Water Quality Monitoring and Analytical Methods in Support of Water Reuse – Part 1

**406 High throughput monitoring of glyphosate in the Lake Erie Basin using IC-ICP-MS: Method development and preliminary data**

*S. Biswas, Nebraska Water Center, University of Nebraska, Lincoln; L. Johnson, NCWQR, Heidelberg University; D.D. Snow, University of Nebraska / School of Natural Resources*

Glyphosate is a broad spectrum, non-selective herbicide that is widely used in agriculture and urban watersheds. According to National Agriculture Statistics Service, glyphosate use in agriculture in the state of Ohio has increased over 20 times from 150 metric tons in 1990 to 3100 metric tons in 2015. Research in Lake Erie watersheds has found glyphosate concentrations in the Maumee River and the western basin of Lake Erie ranging from 0.07 to 1.57 µg/L. While generally considered nontoxic at these levels, some research has indicated that glyphosate could play a role in increasing of dissolved reactive phosphorus loadings from farm fields since the mid-1990s by out-competing phosphate for sorption sites in soil. Apart from the Great Lakes region, detectable concentrations of glyphosate have been found in streams from different parts of the world including the mid-western US, Canada, Argentina, and Switzerland, with concentrations ranging from 0.5 to 70 µg/L.Due to its increasing use throughout the world, and potential ecological risks, new high throughput methods are needed to better understand and characterize runoff patterns in agricultural and suburban watersheds. There are few existing methods that can rapidly measure glyphosate and its primary degradation product aminomethylphosphonic acid (AMPA) at environmental concentrations. We present a newly developed method for glyphosate and AMPA analyses using direct injection ion chromatography inductively coupled plasma mass spectrometry (IC-ICP-MS ) with a detection limit of less than 1 µg/L. This method requires little sample preparation, no derivatization, and provides high sensitivity at low cost. The method provides a good alternative to more elaborate procedures requiring derivatization. To demonstrate the utility of this method, preliminary data on Lake Erie Basin runoff water samples will be presented.

**407 Highly Sensitive Detection of Trace Organic Contaminants in Water Using Automated Online SPE and a Novel Triple Quadrupole LCMS System**

*D. Yang, T. Anumol, T. Sosienski, Agilent; P. Batoon, Agilent Technologies Inc.*

A variety of organic contaminants originating from personal care products, pharmaceuticals, hormones, pesticides, and industrial chemicals are introduced into the environment through domestic and industrial wastewater. These molecules are collectively known as the trace organic compounds (TOrCs) and commonly detected in a variety of resources. Although not acutely dangerous individually, long-term synergistic exposure due to mixtures of these compounds are still to be determined. While studies on long-term/chronic toxicity are yet to be published, it is very important to accurately monitor their presence in environments at trace levels. This requires a methodology to quantify TOrCs with high sensitivity and throughput. Automated online SPE solution fit in well and provides advantage to enrich the analytes for better sensitivity. With minimal human intervention, it improves the throughput of testing lab and measurement precision. TOrCs captured on polymer-based PLRP cartridge were eluted using a linear gradient onto a reversed phase C-18 analytical column for separation and detection. The novel LC-MS/MS is designed to address many challenges faced by routine production labs and high-throughput academic labs. Innovative technologies within the instrument allowed for reduced overall footprint, while conserving the comparable performance level. Innovations, such as VacShield, reduces the need for user intervention for system maintenance. Further, the use of online SPE significantly lowers sample volume, solvent usage while improving robustness and ease of use. Our results demonstrated that most of the analytes could be detected at 1 ng/L with 900uL injection after filtration through a 0.2-µm syringe filter. Samples were analyzed using Agilent Jet Stream electrospray ionization with fast polarity switching. Dynamic MRM (dMRM) transitions for 51 analytes were optimized using an automated tool in MassHunter Acquisition software. Method performance was evaluated using method detection limit (MDL) as metrics of overall sensitivity. The method precisions were calculated based on 6 replicate injections of spiked standards and measurement accuracy has to be within 80-120% for at least 4 of the replicates. Most of the analytes had a %RSD less than 15%.

**408 Rapid Low-Volume Method for N-Nitrosamine Analysis in Recycled Water for Benchtop or Online Monitoring**

*S. Roback, M.H. Plumlee, Orange County Water District; T. Fujioka, Nagasaki University; H. Kodamatani, Kagoshima University*

Current methods for analysis of N-nitrosodimethylamine (NDMA) and other N-nitrosamines require laborious liquid or solid phase extraction followed by gas or liquid chromatography coupled with dual mass spectrometry. The National Research Council recently highlighted the importance of NDMA in recycled water due to its occurrence in treated wastewaters at levels closest to levels of potential human health concern. As such, potable water reuse plants in California are required to monitor NDMA in their finished water. Due to the labor and high equipment costs, NDMA analysis is challenging for many utilities. A novel method for analysis of NDMA and three additional N-nitrosamines in drinking water that requires less time, cost, and sample volume was developed in 2009 and validated in the present study for recycled water. The method requires only a 200 µL direct injection for high-performance liquid chromatography (HPLC) separation and thus the need to collect large volumes of sample (typically 0.5 to 1 L for similar methods) and perform sample extraction is abated. The method uses a UV reactor and chemiluminescence detector to measure N-nitrosamine breakdown products and was validated using a prototype instrument at Orange County Water District following validation criteria from EPA Method 521 for N-nitrosamine analysis. Accuracy and precision for four N-nitrosamines (NDMA, N-nitrosomorpholine, N-nitrosopyrrolidine and N-nitrosomethylethylamine) was acceptable using these criteria. The method reporting limits for the four N-nitrosamines were 1.2, 1.8, 5 and 5 ng/L, respectively, which are equal to or better than most conventional N-nitrosamine methods. The accuracy and precision of the method was also determined for various water matrix types including secondary wastewater effluent, microfiltration (MF) effluent, and finished product water after full advanced treatment for potable reuse. Significantly, this method has been adapted to enable automated online, near real-time NDMA analysis in a pilot treatment system (measurement of NDMA every ~20 minutes) and thus has potential for improving monitoring frequency at recycled water facilities. This may have particular benefits for "direct" potable reuse facilities in which finished water is served soon after treatment.

**409 Assessment of nitrosamines in drinking water using GC-MS/MS with a novel Electron Ionization source**

*D. Barcelo, ICRA / Department of Environmental Chemistry; M. José Farré, Catalan Institute for Water Research (ICRA); D. Cardona, Thermo Fisher Scientific / Marketing CMD*

A gas chromatography tandem mass spectrometry (GC-MS/MS) method for determination of seven N-nitrosamines (NAs) in drinking water is described that utilizes a novel electron ionization source. Nitrosamines are emerging drinking water contaminants linked to cancer by either ingestion or inhalation. Due to their toxicity, nitrosamines are considered as priority pollutants and various countries around the world have already introduced maximum acceptable levels for instance in EPA 521.1. Large volume injection (20 µL), chemical ionization followed by selected ion storage (SIS) resulted as the mass spectrometric method of choice, with detection limits in the range of 1-2ng/L however chemical ionization has problems with robustness and SIS has a narrow linear dynamic range. Solid Phase Extraction (SPE) with coconut charcoal cartridges was applied to extract NAs from 17 real samples collected from different drinking water treatment plants and their distribution networks. In this analysis using a 2 µL injection excellent sensitivity was observed down to 0.003 pg on column (low ppq, w/v) in sample. Outstanding linearity over a range of 0.05-20 pg/µL corresponding to 0.05-20 ng/L in sample with $R^2$>0.999 and RRF % RSD < 5%. Method detection limits were calculated at 0.008-0.045 ng/L. The LOQ was established at between 0.1-0.5 ng/L for all NAs and excellent recoveries were obtained with all values between 70-130% with an average recovery of 93%. The total quantitated nitrosamine amount in the seventeen drinking water samples ranged between 0.9-4.5 ng/L. Here the use of a novel electron ionization (EI) source in conjunction with a triple quadrupole mass spectrometer provides the sensitivity and selectivity to analyze nitrosamines in drinking water at low part per trillion (ppt) levels with low liquid injection volumes and without the requirement for SIS or chemical ionization.

**410 Development of comprehensive libraries for water quality monitoring: The case of per- and polyfluoroalkyl substances (PFASs) in commercial products**

*W. Li, University of California, Davis; T.M. Young, H.N. Bischel, University of California, Davis / Civil and Environmental Engineering*

Per- and polyfluoroalkyl substances (PFASs) are highly persistent and used widely in industrial and consumer applications (e.g., fire extinguishers, non-stick pans, and food packaging). Municipal and industrial run-off has been suggested to be the main source of PFASs. Over 4730 PFASs with CAS number are commercially available, yet due to analytical limitations, research on the fate and effects of PFASs typically focuses on a small subset of chemicals. Several PFASs have been detected ubiquitously in the environment and may be linked to cancer, elevated cholesterol, and immune suppression. Industries have adapted with new structures of some emerging PFASs (e.g., shorter carbon perfluoroalkyl chains) render these compounds more mobile and difficult to treat. The historical approach of measuring individual compounds in these products and the environment is an inefficient way to identify problematic emerging PFASs. Fortunately, advances in analytical techniques, specifically High Pressure Liquid Chromatography Quadrupole Time of Flight Mass Spectrometry (HPLC-Qtof-MS/MS), now enables identification of thousands of organic substances in complex chemical mixtures that make up commercial products or environmental samples. The goals of this study were to build a comprehensive Personal Compound Data Library (PCDL) with spectra from multiple sources and to challenge the library with samples of aqueous film forming foam, which are suspected to be important sources of PFASs to the environment. The PCDL was constructed with 3480 chemicals from multiple sources including in house standards, MassBank, MZCloud, the Norman Network PFAS suspect list, literature reported fragmentations and theoretical fragmentations. The method qualified 11 PFASs with various structures in the samples of aqueous film forming foam (AFFF) produced in 1999 by 3M company. The presentation will highlight opportunities and challenges of suspect screening approaches for monitoring trace organic chemicals. Most studies continue to focus on investigating one or a select suite of compounds at a time due to limited resources for commercial standards, a large number of candidates, lack of effective qualifiers, inefficient fragmentation, matrix effects, and small linear windows for calibration curves. Broad screening techniques are expected to provide value in the detection of whole classes of chemicals like PFAS in complex aqueous mixtures such as wastewater effluent and recycled water.

**411 Wastewater Reuse and Chemical Contaminants of Concern: Understanding Water Quality and Community Perceptions**

*M.L. Hedgespeth, North Carolina State University / Department of Forestry and Environmental Resources; M. Strynar, USEPA / National Exposure Research Laboratory; D. Shea, NC State University; J.A. Delborne, North Carolina State University / Department of Forestry and Environmental Resources; D. Rashash, North Carolina State University / NC Cooperative Extension; E. Nichols, NC State University / Forestry and Environmental Resources*

The city of Jacksonville, NC, uses a forested land treatment site (LTS) to reuse its municipal wastewater by applying secondary treated effluent to forest soils via slow-rate irrigation. Although such forested systems have been utilized for decades in the US, they have only recently been investigated in terms of their roles as a source of emerging contaminants into the environment. Population growth and limited land-expansion opportunities are now driving discussions for alternative means to expand the capacity of the Jacksonville LTS, with the potential for wastewater application to surrounding agricultural land. Our project goals are to characterize the potential human health risks of chemical contaminants of concern in land-applied wastewater at the Jacksonville LTS and to better understand community values and perceptions of alternative wastewater reuse to agricultural lands. Preliminary data from suspect-screening and targeted chemical analyses of water samples indicate the input of organic chemical contaminants at the LTS from wastewater into surface and ground water. Studies of such sites in other areas of the country have demonstrated that citizens often have concerns about their lack of involvement in decision-making processes and health and safety issues regarding wastewater reuse; therefore, survey data obtained from a Community Involvement Group (CIG) provides us with information on local perceptions and values regarding current, non-traditional wastewater use and risks, as well as options for alternative water reuse in the future. Overall, the CIG will work together with the project's leadership team to formulate appropriate strategies to communicate project findings to the broader public.

**412 Potable Reuse and Microbial Risks – a Critical Review and Comparison of Risks between Planned and De Facto Reuse Scenarios**

*J. Soller, Soller Environmental, LLC; S. Eftim, ICF; S. Nappier, USEPA*

There is an increasing interest in recycling water for potable reuse purposes which makes it important to understand the associated microbial risks. To better understand these risks, we conduct numerical simulation analyses to compare risks from a series of representative *de facto* reuse, indirect potable reuse (IPR) and direct potable reuse (DPR) scenarios using a previously published QMRA methodology and literature review results. Variables in the analyses included: (for *de facto* reuse) the percent wastewater contribution in surface water and the environmental residence time in days; (for IPR) advanced water treatment facility (AWTF) treatment train choice, the percent AWTF contribution to the source water, and time between blending and drinking water treatment in days; and (for DPR) AWTF treatment train and relative level of disinfection for DPR. Additionally, the *de facto* reuse simulation results were compared to a *Cryptosporidium* spp. database collected for the Long Term 2 Enhanced Surface Water Treatment Rule's Information Collection Rule (ICR) and to a systematic literature search of norovirus (NoV) densities in ambient surface waters. The *de facto* simulation comparison revealed that a wastewater contribution of 1% in surface waters and a residence time of 90-days most closely match the ICR dataset. These conditions were then modeled for IPR simulations. Additionally, the simulation comparisons suggest that use of NoV data collected from ambient waters may overestimate microbial risks, in contrast to the use of NoV data from raw sewage. Overall, the simulated predicted risks from IPR and DPR scenarios were consistently lower than those for the *de facto* reuse scenarios. Collectively the analyses provide additional insight about the microbial risks associated with various potable reuse scenarios and highlight the need to carefully consider drinking water treatment choices when wastewater is a component of any drinking water supply (whether *de facto*, IPR, or DPR).

**413 Flow cytometry for rapid detection, enumeration, and characterization of waterborne viruses**

*H. Safford, University of California, Davis / Civil and Environmental Engineering; H. Bischel, EPFL – Swiss Federal Institute of Technology / Civil and Environmental Engineering*

The ability to reliably monitor waterborne viruses is essential to ensuring safe water treatment, recycling, and reuse. Waterborne viruses pose significant direct health risks. Moreover, because removal requirements are higher for viruses than for other waterborne pathogens, monitoring virus removal is a conservative approach to assessing the effectiveness of water-treatment processes. Unfortunately, conventional methods of virus monitoring are limited by low sensitivity, extended time needed to obtain results, and numerous other factors. Flow cytometry (FCM)—the analysis of particles based on how they scatter light and fluoresce when passing through a laser beam—offers an alternative approach. Recent advances in FCM have made it a viable tool for water-quality monitoring. Numerous researchers have demonstrated the value of FCM for analysis of waterborne bacteria. This study examines applications of FCM for rapid detection, enumeration, and characterization of waterborne viruses (also known as flow virometry). Specifically, we optimize protocols of FCM-based analysis of four strains of indicator bacteriophages (T4, x174, 6, and MS2) representing a range of sizes, morphologies, and nucleic-acid structures. We then test the optimized protocols on spiked samples of environmental waters (tap water, river water, rainwater, and wastewater taken from three treatment stages). The results build the case for incorporating FCM as a routine monitoring approach in a variety of water treatment and reuse scenarios, including direct potable reuse.

## Fate and Effects of Chemicals from Diffuse Sources and Stormwater – Part 1

**414 Science-based regulatory approaches for addressing stormwater pollution from diffuse sources**

*K. Moran, TDC Environmental, LLC*

Traditional water pollution regulatory approaches, such as those embodied in the US Clean Water Act, stem from the assumption that pollution comes from large facilities like major industries. Due in part to the success of traditional regulatory programs – and in part to the increased use of specialty chemicals in ordinary products – the main sources of water pollution have shifted to "diffuse sources" like consumer products and pesticides. These shifts demand a shift in water quality regulatory approach. Government agencies in the state of California are responding to this challenge through three major regulatory programs. Scientific research provides key data for these programs by identifying pollutant sources, demonstrating linkages between pollutant sources and surface waters, and detailing the environmental impacts of diffuse pollutants. California Department of Toxic Substances Control's (DTSC's) Safer Consumer Products Regulatory Program is currently piloting its authorities to protect aquatic ecosystems. In May 2018, California municipalities petitioned DTSC to address zinc in vehicle tires (one of two major zinc sources in urban runoff). These California agency efforts are informed by the practical experience and the science behind the first major US regulatory program to address a diffuse water pollution source (copper in vehicle brake pads). Using science linking pesticides application methods to urban runoff loads, California Department of Pesticide Regulation's Surface Water Protection Program has adopted regulations addressing urban runoff pesticides pollution and has expanded scientific review of new pesticide registration applications. California State Water Resources Control Board's Strategy to Optimize Resource Management of Storm Water proposes to integrate California and Federal pesticides regulatory authorities into its urban runoff Clean Water Act compliance program. This change could speed cleanup of pesticides water pollution while saving California state and local governments millions of dollars. Ultimately, better informed product design could avoid water pollution. Many major corporations now voluntarily integrate chemicals safety screening into the early phases of product design. Current screening methods have limited capacity to address diffuse urban runoff pollution. Additional scientific information – and better predictive modeling tools – have the power to inform a clean water future.

**415 Roads to ruin: The threats of urbanization to conservation of a sentinel species**

*B. Feist, NOAA Fisheries – Northwest Fisheries Science Center; E. Buhle, Northwest Fisheries Science Center NMFS; D.H. Baldwin, NOAA Fisheries / Northwest Fisheries Science Center; J.A. Spromberg, Northwest Fisheries Science Center – NMFS / Northwest Fisheries Science Center; S. Damm, US Fish & Wildlife Service; J. Davis, US Fish & Wildlife Service / Division of Environmental Assessment and Restoration; N. Scholz, NOAA Fisheries / Northwest Fisheries Science Center*

Since the late 1990s, coho salmon adults returning to their natal urban streams in Puget Sound experience high rates (e.g., 40-90% of run) of spawner mortality syndrome. Evidence suggests that urban stormwater runoff is the likely causative agent and that this high mortality may threaten wild coho populations, particularly in urbanizing basins. The ability to identify basins currently at risk for this syndrome is critical to conservation efforts. We looked at the relationship between the mortality syndrome (time series of coho spawner survey data from 51 streams distributed across an urban gradient in the Puget Lowlands) and basin scale habitat conditions (time series of nationally available geospatial data, including seasonal precipitation) to better understand the landscape characteristics most associated with the syndrome and to generate predictive maps of mortality rates in unmonitored basins. Structural equation modeling revealed a latent urbanization gradient that was associated with road density and traffic intensity, among other variables, and positively related to mortality, which is consistent with other studies that suggest motor vehicles are the likely source of a chemical mixture that washes off urban landscapes into coho spawning streams. Across years within sites, mortality increased with summer and fall precipitation, but the effect of rainfall was strongest in the least developed areas and was essentially neutral in the most urbanized streams. We used the best-supported structural equation model to generate a predictive mortality risk map for the Puget Sound Basin. The predictive mortality map identified likely hotspots for coho spawner die-offs in unmonitored basins across the gradient of urbanization in Puget Sound. Our analyses improve our understanding of the interplay between urbanization and climatic drivers of the mortality syndrome, are easily transferable to other regions, and can be used for siting green stormwater infrastructure in the current built environment and in future development scenarios.

**416 Assessing Acute Sublethal Effects of Stormwater Runoff on Coho Salmon**

*J. Prat, WSU / Puyallup Research & Extension Center; J. Davis, US Fish & Wildlife Service / Division of Environmental Assessment and Restoration; N. Scholz, NOAA Fisheries / Northwest Fisheries Science Center; J. McIntyre, Washington State University*

Urban stormwater runoff poses a direct threat to the health of aquatic ecosystems. In the Pacific Northwest, coho salmon (*Oncorhynchus kisutch*) are recognized as a sentinel species for stormwater impacts due to their acute lethal response. Research to date has been directed towards understanding and preventing lethal impacts of urban runoff to coho salmon. In direct exposures to road runoff, coho experience 100% mortality within 24 h. The current study aims to determine what dilutions of road runoff are necessary to prevent mortality and to assesses potential sublethal effects on coho salmon exposed to urban runoff. Pilot experiments show mortality occurs within the first 24 h of exposure and that dilutions of >90% are necessary to prevent mortality. Continuing research will use stormwater dilutions to assess sublethal impacts to coho exposed to runoff, including DNA damage, hormone imbalances and gene expression patterns. Indicators of sublethal physiological stress in coho could imply threats to survival and reproductive success at stormwater concentrations much lower than previously hypothesized. Gaining a comprehensive understanding of stormwater toxic effects is critical for implementing appropriate regulatory actions to protect coho salmon and other organisms exposed to urban runoff.

**417 Tire leachate recapitulates the pathophysiology, unique sensitivity, and mortality of coho salmon acutely exposed to urban road runoff**

*J. McIntyre, Washington State University; J. Lundin, NOAA NMFS; J. Cameron, NOAA Fisheries / Northwest Fisheries Science Center; J. Prat, Washington State University / Puyallup Research & Extension Center; K. Peter, University of Washington Tacoma / Center for Urban Waters; E.P. Kolodziej, University of Washington, Tacoma/Seattle / Center for Urban Waters Interdisciplinary Arts and Sciences / Civil and Environmental Engineering; J. Davis, US Fish & Wildlife Service / Division of Environmental Assessment and Restoration; N. Scholz, NOAA Fisheries / Northwest Fisheries Science Center*

Coho salmon (*Oncorhynchus kisutch*) spawners returning to spawn in streams receiving urban road runoff suffer high rates of pre-spawning mortality. Direct exposure of spawners to road runoff causes a significant loss of blood ions, drop in pH, and increase in hematocrit, followed by death within hours of exposure. Neither the pathophysiology nor the mortality is seen in concurrently exposed chum salmon (*O. keta*). Contaminants in road runoff are dominated by vehicles sources including fluid leaks, and particulates from exhaust emissions, brake friction materials, and tire wear. Chemicals that leach from tires or tire particles can be acutely toxic to aquatic animals including fish. We tested whether particles from tires could leach sufficient toxic chemicals into water to be acutely lethal to coho salmon. Fine tire particles were generated and placed in a 100-mm mesh filter sock, inserted into an HDPE filter housing, and continuously leached with a fixed volume of clean well water for 22 h. The resulting filtrate (leachate) was essentially clear and devoid of visible particles. Adult coho salmon returning from Puget Sound were placed in well water or a dilution of well water and tire leachate. The lowest concentration that killed all coho spawners within 5 h (0.32 g/L) was used for subsequent testing. At this concentration, all coho exposed to the tire leachate died within 24 h whereas none of the exposed chum spawners died. Finally, blood sampled from coho exposed for 3 h to 0.32 g/L tire leachate showed significant loss of Na and Cl, drop in pH, and increase in hematocrit whereas the blood of chum concurrently exposed did not show these changes. Tire particles may be an important source of the unknown chemicals contributing to pre-spawning mortality in coho salmon exposed to urban road runoff.

**418 Screening of stormwater runoff for environmental contaminants following wildfires in Northern California**

*J. Kinyua, California Dept of Toxic Substances Control / Environmental Chemistry Lab; M. Wang, ECL California Dept. of Toxic Substances Control / Enviromental Chemistry Laboratory; T. Jiang, California Department of Toxic Substances Control / Environmental Chemistry Laboratory; R. Sutton, M.D. Sedlak, San Francisco Estuary Institute; R. Fadness, California State Water Resources Control Board – North Coast Region; J. Park, California EPA / California Department of Toxic Substances Control*

Stormwater runoff picks up pollutants that are present on the landscape during dry days and transports it to downstream areas. It is widely known as a major source of environmental contaminants. In late 2017, wildfires ripped through Northern California's Sonoma, Napa and Mendocino counties, affecting > 115,000 acres of land and destroying ≈ 7000 structures across the state. To evaluate the possible effects of these fires on the types of pollutants in stormwater, and subsequently the ecological impact in San Francisco Bay and the coastal marine environment, we monitored stormwater collected after the wildfires using a non-targeted analytical (NTA) approach. A total of 25 stormwater samples were collected from Napa, and Sonoma counties during two storm events in November 2017 and January 2018. Samples were extracted using solid phase extraction on Hydrophilic-Lipophilic Balance (HLB) and Weak Anion-eXchange (WAX) cartridges. Instrumental analysis was carried using Agilent's 6550 liquid chromatography coupled to quadrupole time-of-flight mass spectrometry (LC-QToFMS) in both positive and negative electrospray ionization (ESI) modes. Identification and confirmation of compounds was facilitated using suspect and non-target screening techniques on Agilent's Masshunter Qualitative Analysis, Profinder, Mass Profiler Professional and Personal Compound Database and Library Manager (PCDL) software. Our in-house databases and libraries contain a wide range of compounds including per- and polyfluoroalkyl substances (PFASs), pesticides, organophosphate flame retardants (OPFRs), and a partial list (≈ 1300 compounds) of a wide range of compounds found on EPA web-based CompTox Chemistry Dashboard. Preliminary screening results tentatively identified the presence of a range of compounds including herbicides and substances present in consumer products. We will present details of the NTA workflow used in the identification of the compounds detected, and an in-depth comparison between the results from the different counties over the two rain events. In addition, we will compare the time series samples to monitor any significant attenuation in contaminants from the initial storm water samples collected after the wildfire. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

**419 Statistical Modeling and Sampling Design Optimization for Monitoring Pollutant Trends in San Francisco Bay Urban Stormwater**

*A. Melwani, Applied Marine Sciences, Inc. / Biological Sciences; D. Yee, San Francisco Estuary Institute; L. McKee, San Francisco Estuary Institute / Center for Environmental Research and Sustainable Technology*

The Regional Monitoring Program for Water Quality in San Francisco Bay (RMP) conducts stormwater loadings studies at small tributaries in the San Francisco Bay region. Here, a statistical framework to optimize the sampling design for monitoring of trends in loads of pollutants of concern at small tributary sites was developed. The longest-running time series of tributary monitoring for polychlorinated biphenyls (PCBs) on the Guadalupe River (2003-2014) was selected as the case study for this work. The statistical approach builds upon the turbidity surrogate methodology that has been employed in tributary monitoring by the RMP since 2003. A two-stage statistical modeling technique was developed to incorporate the significant turbidity-PCB relationship that exists, and evaluates climatic, seasonal, and inter-annual factors as additional potential drivers of PCB loads. After accounting for climatic factors related to antecedence and local watershed precipitation in the statistical model, no significant linear inter-annual trend in PCB loads for the period 2003-2014 was found. Subsequent power analysis of the statistical approach indicated a discrete-based sampling methodology could achieve > 80% power to detect linear declines of 25% or greater in PCB loads, over a 20-year period. Analysis of composite-based sampling designs indicated that this approach was less sensitive to trends, and could only detect larger trends (>75%) over 20 years. Overall, the results of this work suggest that statistical models can be used to control for climatic variation in PCB loads from watersheds, such that trends can be better detected using traditional discrete sampling methods. To further expand this work to a broader context will require monitoring in additional watersheds to test if the proposed approaches to improve trend detection are more widely applicable in San Francisco Bay.

**420 An Analysis of Chemical Contaminants in Sediments and Fish from Cocos Lagoon, Guam**

*S.I. Hartwell, D.A. Apeti, A. Pait, NOAA NOS / National Centers for Coastal Ocean Science Center for Coastal Monitoring and Assessment; A. Mason, DOC / NOAA / National Centers for Coastal Ocean Science, Stressor Detection and Impacts Division / Monitoring and Assessment Branch*

The US Coast Guard operated a Long Range Navigation (LORAN) station on Cocos Island at the southern end of Cocos Lagoon, Guam, from 1944 to 1963. Disposal of materials from the operation of the station are suspected of resulting in chemical contamination of the island and surrounding waters. To help Guam EPA address this, the NOAA/NOS National Centers for Coastal Ocean Science (NCCOS) collected sediment and fish samples for chemical contaminant analysis throughout Cocos Lagoon in May 2015, with local partners. Results of the analysis indicated low levels of most chemical contaminants in sediments. The organochlorine insecticide DDT was somewhat elevated in sediment on the northern end of Cocos Island, exceeding a NOAA sediment quality guideline. Elevated levels of polychlorinated biphenyls (PCBs) along with the pesticide DDT, however, were found in most fish collected adjacent to Cocos Island. A number of the fish contained concentrations of both PCBs and DDT above subsistence and recreational fisher Screening Values established by the US Environmental Protection Agency. Lower concentrations of PCBs and DDT were found in fish from other areas of Cocos Lagoon, however, some were above the subsistence Screening Value for PCBs. Additional sampling using passive water samplers around the island is in progress to assess whether PCBs and DDT are being transported in the water column either as a result of surface water runoff, or through groundwater inputs from Cocos Island that could subsequently be taken up by fish and other marine organisms in the area.

**421 Total Aluminum: Not Totally Relevant for Water Quality Standards**

*A.C. Ryan, S.A. Tobiason, R.C. Santore, Windward Environmental, LLC; A.B. White, E.M. Day, S.J. Veenis, A.R. Groffman, D.J. Carlson III, Los Alamos National Laboratory*

In a large dataset spanning 10 years and more than 100 surface water sampling locations on the Pajarito Plateau, New Mexico (NM) aluminum (Al) concentrations were evaluated in unfiltered and filtered samples (10, 1, 0.45, and 0.2 mm filters). Observed Al concentrations often exceeded ambient water quality criteria (AWQC) regardless of filter size and sample location. Al concentrations upstream and downstream of developed areas within and around Los Alamos National Laboratory (LANL) were similar. Solubility calculations showed that most Al concentrations were over-saturated with respect to amorphous $Al(OH)_3$(s), regardless of filter size. EPA 1988 and 2017 proposed Al AWQC are based primarily on total Al effect concentrations calculated from toxicity tests using soluble Al salts. Potential contributors to observed toxicity in these AWQC toxicity databases are only dissolved (ionic) or freshly precipitated (e.g., amorphous $Al(OH)_3$(s)) forms of Al. In contrast, most natural waters would rarely be expected to contain amorphous $Al(OH)_3$(s), but would frequently be expected to contain aluminosilicates – a stable mineral form of Al that is not bioavailable, but can be present in particulates smaller than 1 mm. In the current dataset, total Al concentrations in wet weather samples were strongly associated with elevated suspended sediment concentrations, suggesting that aluminosilicates contribute to AWQC exceedances. Spectroscopic analyses verified aluminosilicate particles in 1-mm filtrates. While 10-mm or 0.45-mm filtrates yielded fewer AWQC exceedances than total Al measurements, evidence indicates aluminosilicates were still retained in filtrates and contribute to exceedances. In order to more accurately measure AWQC exceedances, preparation of environmental samples should differentiate bioavailable and non-bioavailable Al forms. Because size ranges of amorphous $Al(OH)_3$(s) and aluminosilicates overlap, a sample preparation protocol that solubilizes amorphous $Al(OH)_3$(s), but that does not solubilize aluminosilicates, could be used prior to filtration. However, filtration with 0.45-mm filters may still retain non-bioavailable aluminosilicates in environmental samples, and depending on the particle size distribution, smaller pore size filters may be needed. Further development/validation of such criteria implementation protocols is necessary. This uncertainty overshadows numerous 303(d)-listed waters impaired by total recoverable Al and Al TMDLs already completed.

## Dealing with Bias in Environmental Research: Case Studies and Practical Strategies

**422 Biases and Conflicts of Interests in Environmental Science: Development of Practical Solutions**

*C. Lehman, Dow Chemical Company / Industrial Biosciences; T. Canfield, USEPA / National Risk Management Research Laboratory; V. Forbes, University of Minnesota / Ecology, Evolution & Behavior*

The National Academy defines bias as "… positions taken that are largely intellectually motivated or that arise from the close identification or association of an individual with a particular point of view…" It is well-recognized that biases are present in science, regardless of sector and that they can be introduced anywhere in the scientific process from project development, data collection and assessment to publication and peer review. Social, ethical, and financial influences often enter into our decisions; but, as ethical scientists, we attempt to minimize biases. While there are many practical solutions to increasing transparency and minimizing bias (e.g., publication of raw data, double-blind peer reviews, involvement of 'neutral' third parties), few have gained traction to date. Until ideas for reducing biases are introduced and gain wider acceptance, few will be willing to proactively do what it takes to affect change. This presentation as well as others in this session build upon previous SETAC North America sessions (two in Salt Lake City in 2016 and one in Minneapolis in 2017). We have developed this session to provide a platform for continued dialogue and development of practical solutions to minimize bias in environmental science.

**423 Study Design Bias or Bias by Design: Impact of Measurement Endpoint Bias**

*D.J. Fort, Fort Environmental Laboratories, Inc.*

Evolution of higher-tiered, modern-day toxicological bioassays has led to the development of technically-sophisticated measurement endpoints to support interpretation of results produced. Development and incorporation of these endpoints into test designs is critical in support of the highly specific objectives of these assays. Because many of the endpoints incorporated into the design are highly focused and the number of endpoints needed to provide evidence to support a response is often substantial. Measurement endpoints capable of discerning specific effects, such as various aspects of endocrine disruption, are selected over endpoints which would assist in discriminating against overt toxicity or toxicity induced by an alternative mechanism. Incorporation of a more balanced set of measurement endpoints would alleviate issues in interpretation of results resulting in ambiguous conclusions. Two case studies in which additional endpoints assisted in clarifying results and conclusions drawn will be discussed. Ultimately, these case studies demonstrate that consideration of the measurement endpoints used at the study design level reduced measurement endpoint bias and ultimately impact on interpretation bias in the conclusions drawn.

**424 How do you know: When does bias against uncertainty get in the way of making a decision?**

*S. Raimondo, USEPA / Gulf Ecology Division*

Bias in risk assessment has been attributed to the varying perspectives and goals of individuals and their organization or sector. Indeed, offices or agencies even within a sector can have different missions (e.g., protection of listed species, sustainability of food production) and individuals are charged to follow the mission of their respective agency. This is not wrong, and individuals should advocate for the mission that they signed up to achieve. By their nature, properly designed and executed scientific studies are unbiased, as the scientific method controls for factors that would introduce bias and isolates the relationship of an endpoint to measurable factors. It follows that the role of peer reviewers is to ensure that studies are properly designed and conducted in such a manner that, once published, scientific results can be used with confidence. In practice, however, this is not always the case and the value and validity of published research results are often debated. The root of such debates is often attributed to sector bias, but in actuality it is the uncertainty surrounding those results that prevent people in all sectors from trusting them wholly, too often paralyzing the decision making process. Uncertainty is inherent in all science; no research results will ever have 100% certainty. The root of individual and sector bias is discomfort with uncertainty and never being able to truly know which side of the confidence interval an environmental reality may actually lie for any given scenario. If the collective research community was able to minimize uncertainty to unmeasurable levels, sector bias would cease to exist. This presentation uses examples for various environmental models to demonstrate how individual and sector perspectives lie in different regions of the proverbial cone of uncertainty, and demonstrates that what may present as bias is often an affinity towards a particular location within uncertainty bounds. If individuals or sectors are all existing within the same space of uncertainty, then no one perspective is wrong. Rather than forcing agreement on where within an interval of uncertainty the "truth" lies, efforts of the collective research community should focus on identifying, reducing, and characterizing uncertainty. As the breadth of uncertainty decreases, so will the distance between perspectives of individuals and sectors within the regulatory community.

**425 Reducing bias through multi-sector collaborations**

*C. Borgert, Applied Pharmacology & Toxicology, Inc.*

Bias in scientific research can be defined as the over-reporting of false-positive or false-negative results, which are those that cannot be replicated or turn out to be invalid when applied beyond the experimental construct. Thus, bias is a function of how research is conducted, interpreted and characterized. Multi-sector collaborations (MSCs) are proffered as a means of reducing bias, but their success depends upon the extent to which inherent impediments are recognized and addressed. Particularly within the realm of public and environmental health, contributors may have divergent views of the problem to be addressed and may disagree on the underlying principles of what science itself requires. Participation in MSCs can be motivated more by a desire to advance agendas important to particular sectors rather than to achieve solutions that provide general benefits. In some instances, maintaining the perception of being at odds with other stakeholder groups is highly valued, particularly when particular interest groups consider preservation of an issue or controversy more beneficial than problem-solving. The opposite occurs when stakeholders value a reputation as cooperative and conciliatory more highly than finding optimal solutions. These impediments can render "collaboration" mere "negotiation" or even "confrontation." The most critical factor in overcoming these impediments is the ability to recognize them and to confront them candidly. These must be addressed in order to determine whether a true collaborative effort is even possible. MSCs should begin with a clear problem formulation step that achieves the full consensus of all participants. There must also be forethought regarding the underlying principles involved and a plan for identifying incongruent views of the collaborators, e.g., what is meant by relevance and quality of data, what is the appropriate role of expert judgment, and whether scientific objectivity or precautionary values are appropriate for the endeavor. To decide whether a true "collaboration" is possible, it is critical to fully vet these principles and develop a clear statement regarding areas of consensus and disagreement, the motives for participation, potentially conflicting goals, and the types of outcomes that will benefit each sector. To the greatest extent possible, team approaches should be used in order to reduce the inherent tendency toward negation rather than collaboration.

**426 Citation trends in the ecotoxicology literature and what they tell us about possible biases**

*M.L. Hanson, University of Manitoba / Department of Environment and Geography; R.S. Prosser, University of Guelph / School of Environmental Sciences; L. Deeth, University of Guelph / Department of Mathematics and Statistics*

There seems to be a reticence to engage with the totality of the pesticide ecotoxicology literature, especially papers that report few or no effects or low risk to non-target organisms. We hypothesized that these studies would have fewer citations than studies that report significant effects or risk for the same compound, and this would be unrelated to the strength of the study, e.g., high quality studies with few or no effects would be cited less frequently than studies of lesser quality that reported effects. To investigate this, we examined a subset of literature around the herbicide atrazine and responses in fish, amphibians, and reptiles. We found that papers reporting an effect had significantly more citations per year than those that did not ($p < 0.05$). There was no significant relationship between the strength of the study and number of citations, but a general trend for weaker studies to have greater number of citations. The impact factor of journals was not positively correlated with the strength of the study methods, but studies that reported effects were published in journals with a greater mean impact factor than those that reported no effects ($p < 0.05$). This analysis reveals evidence of citation bias within the pesticide ecotoxicology literature, as well as bias by journals to publish studies that report effects, regardless of study quality. We have built on this initial work and are examining citation trends for articles published in the journal Environmental Toxicology and Chemistry (ET&C). Specifically, we focused on papers reporting effects of pesticides since ET&C's inaugural issue in 1982 through to 2012 and limited the analysis to the titles only

(>700 papers). A number of questions were addressed in addition to role of 'effect' or 'no effect' and findings will be presented. These included; does author affiliation influence citation rates (e.g., academic, industry, government), does the class of specific pesticide matter, and have trends changed through time? In conclusion, ecotoxicologists seem to have a problem with 'no effect', whether publishing, interpreting, or citing such findings. This bias towards seeing 'effects' everywhere has the potential to severely hinder our ability to identify real problems and work collaboratively to address these challenges. Recommendations to address this behaviour will be provided.

**427 The role of transparency in enabling reproducibility and reducing bias**

*A. LeHuray, Chemical Management Associates LLC*

In March 2018, the US Environmental Protection Agency (EPA) proposed a rule titled *Strengthening Transparency in Regulatory Science* (83 Fed. Reg. 18768). The title is misleading, however, because EPA proposes to restrict its increased focus on transparency to only dose-response data and models, to only final regulations, and to only *pivotal studies*, as narrowly defined in the proposed rule. Worldwide, scientists and science organizations have recognized the crucial role of transparency to the crux of the scientific enterprise: reproducibility. Any agency that promulgates environmental regulations should require that science considered as possibly key or pivotal to a regulatory purpose must meet a standard of transparency. The role of environmental agencies is to translate and distill research results into regulations, guidance, and policies that have significant impacts in the real world. It is therefore an obligation to ensure use of the best available science on any issue, for any important matter of policymaking. Whether in the "pure" or regulatory sciences, the principal reason for requiring transparency of scientific data is to enable reproducibility studies and validation. An inability to reproduce or validate a research result is often related to a bias in the original study. For an agency to require transparency but ignore findings of irreproducibility defeats the purpose. Thus it is important to develop mechanisms of scientific review that incorporates risk of bias and validation studies. Governments belonging to the Organization for Economic Cooperation and Development require that scientific testing data submitted by industry as the basis for product registrations, hazard evaluations, or other purposes comply with *Good Laboratory Practices* (GLP). The reason for the requirement is to ensure that the Agency's evaluations are based on *data of sufficient quality, rigor and reproducibility*. Recognizing that not all provisions specified by formal GLP programs can be applied to all studies, the concept of the *spirit of GLP* is often adopted by regulatory agencies and study sponsors. GLP and the spirit of GLP should be adopted by environmental agencies as a requirement for all science considered as a possible basis for regulation, guidance, or policy. Doing so would be a step towards reducing bias and enabling replication.

**428 Assessment of chemical risk employing field investigations to address hazard and exposure: Identification and management of bias**

*W.L. Goodfellow, R. Kashuba, N.W. Gard, L.A. Royer, K.R. Palmquist, Exponent, Inc. / Ecological and Biological Sciences Practice*

Emerging contaminants and other stressors that receive heightened public attention often attract investigation because there are increased pressures from management or regulatory agencies to assess the risk, they offer the potential for funding opportunities, or they offer opportunities to address issues of interest to the scientific community. In developing field or laboratory assessments, investigators need to be careful to develop their assessment strategy to not adversely or unknowingly bias the results or interpretation. Determining ecological risk often requires assessing impacts to organisms using field exposures and linking them to laboratory derived toxicological results (effects). For emerging contaminants, information is often limited or rapidly evolving, making it difficult to characterize background concentrations, and the environmental fate and transport, toxicity, and bioaccumulation/biomagnification are often not well understood; therefore, it is possible that environmental samples may not adequately describe the natural variability or range of concentrations to which receptors may be exposed. There is also often pressure to complete assessments of emerging contaminants to understand the ecological risk; however, this pressure may also contribute to bias, when our need for large-scale answers means overlooking the limitations of key underpinning data. Incomplete understanding of the toxicity of the emerging contaminant may also be a source of bias regarding effects. This limited information may potentially increase the chances that the endpoints, modes of exposure, or species evaluated are irrelevant to addressing the overall risk. Using case studies, this presentation will provide examples where the results from field or laboratory studies may be misleading or bias the interpretation of adverse effect beyond what the data can support or what the study was designed to assess. Recommendations for strategies that can be used in managing bias when it is identified will also be provided.

**429 The interaction of different forms of bias in academic research and suggestions for mitigation**

*C.A. Murphy, Michigan State University / Department of Fisheries and Wildlife*

In academic research, numerous forms of bias exist. Research bias can arise because of the structure of academic institution and granting agencies, and their associated reward structures. The scientific research conducted could be biased because of a study design that emphasizes novel results. The particular question the research addresses could be biased because of the reliance and acceptance of significant findings. Other layers of implicit bias exist that include social and gender biases that affect the type and quantity of research generated. In this presentation I will discuss these biases and how they interact, with examples from academic research institutions, and I will address how they affect ecotoxicological research. I will also discuss potential mechanisms to mitigate these biases so that we can come up with solutions to pressing ecotoxicological questions more efficiently and equitably.

## Environment Exposure to Microplastics and Affiliated Toxic Chemicals

**430 Polycyclic aromatic hydrocarbons affiliated with microplastics in surface waters of Bohai and Huanghai Seas, China**

*L. Mai, E.Y. Zeng, Jinan University / School of Environment*

Microplastics (MPs) sized between 0.33 and 5 mm were collected using Manta trawls from ten surface seawater sites in Bohai and Huanghai Seas, China. A total of 1,024 (Bohai Sea) and 132 (Huanghai Sea) MP pieces were classified, including polystyrene foams, polyethylene films and lines, and other plastic pellets, with concentrations of MPs ranging from 3 to 162 particles per 100 $m^3$ (0.012 to 2.96 mg $m^{-3}$). Apretreatment of MPs with 30% $H_2O_2$ in water did not significantly lower polycyclic aromatic hydrocarbon (PAH) concentrations on MPs compared to no $H_2O_2$ pretreatment. Measurements of PAHs carried on the collected MPs indicated that the concentrations of the sum of 16 PAHs were in the range of 3,400-119,000 ng $g^{-1}$. The sources of PAHs in Bohai and Huanghai Seas were highly similar, with petroleum and gasoline probably as the dominant sources. The present study shows the relative importance of MPs in regards to chemical transport in the marine environment. The combination of high concentrations of PAHs affiliated with MPs and the increasing magnitude of plastic pollution in the world's oceans demonstrates the considerable importance of MPs to the fate of PAHs in marine environments.

**431 The influence of particle charge and eco-corona on the entry of nanoplastic into a freshwater food web**

*C. Liddle, Heriot Watt University / School of Life Sciences; A. Cruz-Laufer, University of Exeter / Biosciences; C. Tyler, University of Exeter / Biosciences College of Life and Environmental Sciences; T.S. Galloway, University of Exeter / Biosciences*

Plastic particles are an abundant contaminant in the aquatic environments. Microplastic particles (< 5 mm) are of concern, as they have been demonstrated to enter food webs. However, little is known about their smaller counter parts, nanoplastics (< 100 nm, NP), largely because their quantification in the environment remains a challenge. A small number of studies have quantified nanoplastic uptake via waterborne exposures within aquatic organisms, but not enough is known about how NPs may enter aquatic-food-webs, and what might modulate this entry route. In this study, the entry of nanoplastic into the base of a food web, was quantitively tracked, for the first time. Nanoplastic sorption to *Chlorella vulgaris* Beij. (green algae) and the subsequent dietary transfer of nanoplastic via the algae to *Daphnia magna* (water flea) was studied. The modulating role of nanoplastic surface charge, and eco-corona formation (where particles were coated with humic acids or proteins to simulate the effects of environmental alterations in their surface chemistry), was addressed. Quantification of NP tissue burdens (LOD: 0.08 µg/mg) was enabled using a novel fluorescence bioassay in a high-throughput microplate format, supplemented with airyscan-confocal imaging, to trace the particle interactions with algae-cells and the dietary transfer to *Daphniids*. *Daphnia magna* whole-tissue oxidative stress response was also investigated, as an indicator of NP systemic bioavailability, following dietary transfer. Particle charge had a significant effect on the NP algal-cell-particle sorption, with positive particles showing higher algae-sorption and dietary transfer, than negative or neutral particles. Eco-corona formation had no significant effects under the conditions tested. Bio-imaging confirmed NP-algae localization in the *D. magna* gut, and no alterations in oxidative stress responses were found. In conclusion, we successfully tracked the entry of nanoplastics into the base of a food web, where we found that particle charge will significantly affect the amount of NPs that enter a freshwater food chain. This finding supports that the physico-chemistry of the particle in the environment is an important factor for determining NPs entry into a food web.

**432 Ingestion, bioaccumulation and depuration of nano- and microplastic particles by marine bivalves**

*K. Mladinich, V. Haynes, University of Connecticut / Marine Sciences; B. Holohan, University of Connecticut; J. Ward, University of Connecticut / Marine Sciences*

Plastics debris are introduced into the oceans, through industrial production and as anthropogenic waste. Larger plastics breakdown into nanoplastics (NP) and microplastics (MP) via weathering. Benthic animals, such as suspension-feeding bivalves, are exposed to NP and MP pollutants in coastal waters. Studies have shown that NP and MP negatively affect marine animals on an organ and cellular level. Despite the potential for exposure and toxicological effects, the uptake and accumulation of NP and MP by bivalves is largely unexplored. This study examined the ingestion, egestion, and bioaccumulation of fluorescent polystyrene NP and MP by the blue mussel (*Mytilus edulis*). NP and MP were aged in seawater for 3 days prior to exposure experiments. Mussels were exposed to a 0.1 mg/L/hr concentration of NP or MP for two weeks and then allowed to depurate for one week in filtered seawater. Mussels were fed a standard microalgal diet throughout the 3-week experiment. Whole animals were frozen for later analysis of NP or MP concentrations at the end of each week and feces were collected daily for all 3 weeks and frozen. Tissue and feces samples were analyzed via a scanning fluorescence spectrophotometer for plastic quantification. The concentration of NP in tissue samples did not differ significantly between 7 days and 14 days of exposure, nor did the concentration of MP. After the exposure period, 38.5% of NP and 63.3% of MP remaining in the mussels were egested on the first day of depuration. Feces samples contained higher concentrations of MP during exposure and tissue samples contained higher concentrations of NP during exposure. These results imply that plastic particles are transported in and out of mussels quickly. This study will be used to develop biokinetic models of NP uptake and bioaccumulation in shellfish and help elucidate the potential for these materials to be passed to higher trophic levels including humans.

**433 Sorption of Antimicrobials, Triclosan and Triclocarban, to Polyethylene and Polypropylene Microplastics**

*A. Sanchez, University of Maryland, College Park / Civil and Environmental Engineering / Marine-Estuarine Environmental Sciences; L.T. Yonkos, University of Maryland / Environmental Science and Technology; A. Torrents, University of Maryland / Civil and Environmental Engineering*

Microplastics enter rivers and estuaries through stormwater runoff and municipal wastewater effluent, where they eventually travel to the ocean. Recent research has suggested that billions of microplastics per day may enter U.S. waterways from municipal wastewater. Organic contaminants are known to sorb to plastics at concentrations magnitudes higher than the surrounding water. However, there is relatively little research about the behavior of compounds in pharmaceutical and personal care products, which are concentrated in wastewater. Most work has focused on compounds with only nonpolar moieties, such as polyaromatic hydrocarbons and polychlorinated biphenyls. Therefore, this study examines the sorption behavior of the antimicrobial agents triclosan and triclocarban to microplastics made of high-density polyethylene and polypropylene. In addition, efforts were made to create a standard protocol for fabricating microplastics at different particle diameters, characterizing particle surface area, and measuring the sorption behavior of slightly-polar organic compounds on microplastics. Results will be presented that will show the differences in sorption between particles of different diameters (i.e., surface area) and polymer types. The standardization of these methods will increase the robustness of future research, so that data may eventually inform wastewater policy.

**434 Microplastic is a Vehicle for Pharmaceutical-Transforming Microorganisms**

*A. Porter, Rutgers University School of Environmental and Biological Sciences / Environmental Sciences; S. Wolfson, Rutgers University; L.Y. Young, Rutgers University / Department of Environmental Sciences*

Microplastic is an anthropogenic contaminant that is widely distributed in the environment. As microplastic travels through aquatic systems it will interact with and may bind other environmental contaminants, as well as microorganisms. We propose that microplastic is a vehicle that carries microorganisms and pharmaceutical contaminants, which serve as a source of carbon and energy for microbes, from wastewater treatment into the environment. To study the interaction between microorganisms, microplastic, and pharmaceuticals, we established methanogenic enrichment cultures using anaerobic digester sludge as inoculum and delivered naproxen as the sole carbon source by coating microplastic beads with it. Naproxen is a nonsteroidal anti-inflammatory drug that is frequently detected in wastewater-impacted urban environments. HPLC analysis of primary enrichment cultures showed naproxen loss and accumulation of a metabolite in the aqueous media. Once naproxen transformation was complete, colonized microplastic and planktonic cells from the bulk medium were separated and independently used to inoculate fresh medium containing neat naproxen. Naproxen was again completely transformed in anaerobic microcosms inoculated with transferred microplastic, but no loss was observed with transfers of planktonic cells. Next-generation DNA sequencing showed differences between the two microcosms with respect to the microbial community structure and presence of specific functional genes. Our results demonstrate that microplastic provides a habitat for microorganisms that allows them to be in close contact with each other and with sorbed contaminants that serve as a source of carbon. This creates the potential for the environmental transport of pharmaceutical-degrading microbes on the microplastic surface.

**435 Trophic transfer of microplastics and an associated legacy pollutant from microzooplankton to their predators**

*S. Athey, University of Toronto / Earth Sciences; S. Albotra; C. Gordon; M. Echevarria, University of North Carolina Wilmington; B. Monteleone, University of North Carolina Wilmington / Chemistry and Biochemistry; A. Andrady, NC State University / Department of Chemical and Biomolecular Engineering; A.R. Taylor, University of North Carolina Wilmington / Biology and Marine Biology; S.M. Brander, Oregon State University / Environmental and Molecular Toxicology*

Microplastics, which pose an environmental hazard because they are readily ingested and accumulated by aquatic organisms, are of increasing global concern in the aquatic environment. The plastic attracts and dissolves lipophilic compounds, such as the legacy pollutant DDT, that may leach into the tissues of organisms upon ingestion. This study used larval inland silversides, *Menidia beryllina* and the tintinnid ciliate, *Favella* spp as a predator-prey model relevant to US estuaries, in order to examine trophic transfer of microplastics. LDPE microspheres (10-20µm) treated with the insecticide DDT were used to determine whether the presence of a plastic-associated pollutant can affect plastic ingestion by larval fish and their prey. After allowing ciliates to feed upon either contaminated or virgin microspheres, larval fish (5 dph) were permitted to transiently prey upon them. After the 2 h feeding period, larvae allowed to transiently prey upon plastic-laden ciliates were found to contain up to 320 particles larvae$^{-1}$. Larvae in direct ingestion groups ingested significantly fewer microspheres than those in trophic transfer groups. This suggests trophic transfer from prey could be a significant source of microplastic exposure. Larval silversides ingested significantly more ciliates fed DDT- treated microplastics. Retention time of microplastics in the gut of larval silversides was also investigated. The excretion rate of microplastics integrated over the entire sampling period (2.5h – 72h after feeding) was 0.15 particles h$^{-1}$, with most particles being excreted within 24 h. Fish reared for a further 16 d following a 2 h microplastic feeding had a lower weight than individuals that were not exposed to microplastics. This is the first study to demonstrate the trophic transfer of microplastics in an estuarine predator-prey model. Our results indicate microzooplankton can be vectors for the transfer of microplastics to higher trophic level organisms in estuarine systems and that a brief period of microplastic ingestion can impact growth and development of larval forage fish.

**436 Analytical and in vitro Estimates of Estrogenicity from Simulated Digests of Plastic Items**

*S.L. Coffin, University of California, Riverside / Environmental Toxicology; G. Huang, Guangzhou Institute of Geochemistry; D. Schlenk, University of California-Riverside / Department of Environmental Sciences*

Since their mass production in the 1940's, plastic has become an indispensable part of modern life. Poor management of plastic waste results in the leaking of approximately 8.0 million metric tons of plastic into the world's oceans every year. Over 206 species, including 119 bird species and 41 fish species have been documented to ingest plastic, likely confusing it for prey. Once ingested, plastic may release endocrine-disrupting compounds which may impact development, reproduction and success at the individual level and declining trajectory at the population level. We selected 16 plastic items that are most commonly found ingested by marine animals. We then "digested" these plastic items in fish and seabird laboratory gut mimic models using the digestive enzyme pepsin at pH 2 and shook them for 16 hours at either 28° C (in saltwater) for fish or 40° C (in freshwater) for seabirds. Plasticizer content desorbed into the gut mimic liquid was quantified using solid-phase extraction followed by ultra-high-performance liquid chromatography/tandem mass spectrometry. Polymer types were identified using Fourier-transform infrared spectroscopy. In vitro estrogenicity was assessed using a recombinant cell line. Out of 12 plasticizers analyzed, 4-*tert*-octylphenol (OP), bisphenol A (BPA), bisphenol S, butylbenzyl phthalate and bis(2-ethylhexyl) phthalate (DEHP) concentrations were significantly increased due to digestive gut conditions. Desorption of estrogenic plasticizers from plastic items was significantly higher in the seabird gut mimic than the fish gut mimic. Only micro-sized plastic items (< 5mm) had higher in vitro estrogenicity due to gut mimic conditions. Of the plastic items tested, expanded polystyrene, shopping bag fragments and polypropylene string had both the highest analytically- and in vitro -determinedestradiol equivalency values (EEQ) in both seabird and fish gut mimic conditions (range: 2.8-9.6 ng/g). Enhanced desorption of OP, BPA and DEHP accounted for the higher in vitro estrogenicity. These results demonstrate the need for further research into the endocrine-disrupting effects of plastics once ingested.

**437 Interaction and immunotoxic effects of microplastics in the estuarine worm *Hediste diversicolor* in environmentally relevant conditions**

*M. Revel, N. Yakovenko, T. Caley, Catholic University of the West / Laboratory Mer Molécule Santé; C. Guillet, University of Angers, IBS-IRIS / Cellular and Molecular Analysis Platform; A. Châtel, C. Mouneyrac, Catholic University of the West / Laboratory Mer Molécule Santé*

Since the early 1970s, presence of floating plastic has been reported in marine waters with great accumulation in gyres. In recent years, the presence of plastic debris < 5mm called microplastics (MPs) which result mainly from macroplastic's fragmentation has also been reported in aquatic ecosystems. Several studies have reported that these MPs are persistent and their accumulation has been observed in various aquatic species. The majority of studies have focused on marine species, but much less with continental and estuarine biota. The present study investigates the interaction and the effects of microbeads and a mixture of two types of MPs (polyethylene and polypropylene), frequently found in natural environments, towards the ragworm *Hediste diversicolor* to determine their accumulation in animals exposed through the water phase or sediment. First, to get a better understanding of the interactions between MPs and the ragworm, organisms were exposed to fluorescent microbeads and the tissues were observed under a fluorescent microscope to follow the path of MPs. Then, two concentrations of exposure were selected corresponding to medium and heavily contaminated areas reported for water phase (10 and 100 µg/L) and sediment (10 and 50 mg/Kg) and organisms were exposed for 96h or 10 days following the protocol of the American Society for Testing and Materials (ATSM, 2013). To study the potential toxic effect of MPs, immune parameters have been selected since they are involved in many defense mechanisms against external agents. An average number of MP/worm ranging from 0 to 2.5 and from 1 to 36 was identified in animals exposed to the lowest and the highest concentration of MPs respectively, through water exposure. However, the majority of MPs seem to be located into the worms skin mucus. In worms exposed through sediment, less than 1 particle/worm was found and a higher number of particles were identified in depurated sediment. First results of immunotoxic impact indicates that MPs exposure induced a decrease in coelomocytes viability and in phenoloxydase activity, but no alteration of phagocytic activity was measured. This study brings new results on the potential accumulation and immunotoxic effects of MPs, in environmentally relevant conditions, for the ragworm *H. diversicolor* who plays a key role in the estuarine ecosystem.

## Assessing Contaminant Effects on Early Life Stages of Marine Organisms

**438 Age-dependent partitioning of polychlorinated biphenyls among the brain, liver, kidney and muscle of a coastal fish predator**

*K.D. Prince, C. Angelini, University of Florida / Department of Environmental Engineering Sciences*

Polychlorinated biphenyls (PCBs) are globally- distributed pollutants that bind to adipose tissues found throughout the bodies of multicellular organisms and, at high levels, can induce detrimental health effects. As organisms age from juveniles to reproductive adults, the relative mass of adipose tissue in the brain, liver, muscles and other organs often shifts.

However, it is unclear how these ontogenetic changes may also affect PCB concentrations in different organs, because most studies have measured PCBs in a single organ, whole body composites, or organisms of a similar age. To address this gap, we quantified the lipid content and PCB concentrations of brain, kidney, liver, and muscle samples taken from 15 red drum (*Sciaenops ocellatus*), a large, long-lived predatory fish common to southeastern and Gulf US coastal waters. We discovered that lipid normalized PCB concentrations increase in all four organs as fish age, however their rate of increase was significantly faster in liver, brain and muscle tissues than in the kidney. When multiplied by the mass of each organ, we found that while the liver contributes most to an individual's total body burden for young red drum, muscle tissues contribute most for older individuals when lipid normalized. These findings highlight the importance of ontogenetic shifts in influencing rates and patterns of PCB accumulation.

**439 Impacts of microplastic fibers on Pacific mole crab (*Emerita analoga*) development and mortality**

*D. Horn, E. Granek, Portland State University / Environmental Science & Management*

Microplastic is an emerging pollutant in marine and coastal ecosystems. Millions of tons of plastics are added into these systems annually and are of particular concern due to their persistence in the environment, propensity to attract other pollutants, their toxicity and tendency to degrade into microplastics (particles or fibers < 5mm) making them easily ingestible. Sandy beaches are consistently exposed to plastic debris accumulation from wave action, near shore currents as well as effluent from waste water treatment plants, exposing the infauna to persistent plastic pollution. Pacific mole crabs (*Emerita analoga*),found in the sandy beaches along the Pacific coast, are filter feeders that have been shown to ingest microplastic in previous studies. To assess the impact of polyethylene fibers on the reproductive development of Pacific mole crabs, adult females were exposed to environmentally relevant concentrations of polyethylene fibers (< 1mm) for 2 months during a reproductive cycle. Effects were investigated on offspring development. Our study shows that the exposure and ingestion of polyethylene microplastic debris at environmentally relevant concentrations alters development in Pacific mole crabs and warrants further research.

**440 An assessment of directly ingested and trophically transferred microplastics in larval and juvenile black sea bass (*Centropristis striata*)**

*C. Stienbarger, J. Joseph, University of North Carolina Wilmington / Department of Biology and Marine Biology; P. Carroll, University of North Carolina Wilmington; B. Monteleone, University of North Carolina Wilmington / Chemistry and Biochemistry; A. Andrady, NC State University / Department of Chemical and Biomolecular Engineering; W. Watanabe, P. Seaton, University of North Carolina Wilmington; A.R. Taylor, University of North Carolina Wilmington / Biology and Marine Biology; S.M. Brander, Oregon State University / Environmental and Molecular Toxicology*

Plastic pollution, primarily in the form of microplastics, is the most abundant and persistent form of marine debris. Coastal and estuarine waters are especially susceptible to microplastic pollution due to their proximity to terrestrial inputs and tidal processes that provide favorable conditions for accumulation. Estuaries are critical habitats for early life stage development of commercially important fish species, including the black sea bass (*Centropristis striata*). Trophic transfer of microplastics and associated pollutants is documented, but the impact is still largely unknown. To evaluate the role and effects of microplastic ingestion in this commercially important species, larval and juvenile *C. striata* were exposed to three concentrations (1,000,000 particles $L^{-1}$, 100,000 particles $L^{-1}$, and 10,000 particles $L^{-1}$) of virgin and contaminated 10-20 mm low-density polyethylene (LDPE) microspheres directly in the water and via trophic transfer from prey. Larval fish were also directly exposed to LDPE microfibers, and juvenile fish were exposed to fibers directly and via prey. For trophic transfer treatments, juvenile sea bass (60 days post hatch) were fed larval silversides (*Menidia beryllina*), and larval sea bass were fed single-celled ciliates (*Favella* spp.), both containing plastics. The contaminated microspheres were treated with either 1.9 mg/g of phenanthrene, a polycyclic aromatic hydrocarbon commonly detected on plastics or 12 mg/g of 2,4-di-tert-butylphenol, a hindered phenol added to plastics to prevent thermal degradation during processing, both at environmentally relevant concentrations. Microsphere counts are being obtained for each larva to determine consumption across all treatments after a single 2-h exposure, and RNA-Seq will be conducted to measure gene expression. Juveniles were exposed to microplastics over a 4-d period, and sublethal effects, including oxygen consumption and immune response were assessed at test termination. Whole juvenile fish were also preserved for chemical analysis to determine if the pollutants leach into the body tissues of the fish. We hypothesize that cultured larval and juvenile *C. striata* will be negatively affected by microplastic exposure, chemicals leach into tissues, and microplastics are possibly transferred in greater numbers from trophic transfer than direct ingestion. Results of this study will lend guidance to management of the fishery and inform potential concerns regarding human consumption.

**441 Biomarker Responses of Coral Larvae**

*A.H. Ringwood, UNC-Charlotte / Department of Biology; J. O'Dea, UNC-Charlotte; C. White, University of Montana; M. Lowder, E. Provance, Discovery Place Science; K. Latijnhouwers, V. Chamberland, M. Vermeij, Caribbean Research and Management of Biodiversity*

Coral reef ecosystems are among the most biologically diverse and productive ecosystems on the planet, and provide habitat for a myriad of fish and invertebrates. Therefore, coral reef biologists and conservationists are actively engaged in research for finding ways to improve the recruitment and sustainability of coral species. One common approach has been to use asexual propagation techniques in which broken pieces of coral are glued to a calcium carbonate substrate and placed into the field to restore coral reef ecosystems. Researchers at CARMABI (Caribbean Research and Management of Biodiversity (CARMABI) research station in Curaçao have also recently been working with SECOR (Sexual Coral Reproduction), a program which focuses on rearing larvae in the laboratory to improve settlement and recruitment of coral larvae, and then planting the young coral colonies for repopulating coral reefs in situ. There are concerns about the best habitat for restoration and potential anthropogenic effects of pollutants, including sunscreens. We conducted biomarker studies, especially those related to oxidative stress (the antioxidant glutathione and lipid peroxidation as an indicator of oxidative damage) in adults and larvae of three species of Caribbean corals (*Diploria labyrinthiformis, Tubastrea coccinia, Agaricia humilis*). Very little information has been published regarding biomarkers of antioxidant levels in coral species, and baseline levels of glutathione can serve as a potential indicator of differential sensitivity. Overall larvae had significantly lower gluathione levels than adults, suggesting that larvae may be especially sensitive to algal or environmental stressors. Biomarker studies were also conducted with larvae that were exposed to various benthic algae that could affect settlement and metamorphosis success, and there was evidence of potential allelochemical production by some of the algal species that resulted in oxidative stress. We also worked with larvae of one species of Hawaiian coral, *Montipora capitate*, and conducted preliminary experiments in which larvae were exposed to different sunscreens (including Zn, Ti, and oxybenzone formulations). Understanding factors that can affect recruitment and settlement of coral larvae and the development of sensitive bioassays of larval health are critical aspects of reef preservation and restoration.

**442 Developmental and reproductive effects in grass shrimp (Palaemonetes pugio) following acute larval exposures to thin oil sheens and ultraviolet light**

*P.B. Key, National Ocean Service / National Centers for Coastal Ocean Science; K.W. Chung, B. West, JHT, Inc. / National Centers for Coastal Ocean Science; M.E. DeLorenzo, NOAA / National Centers for Coastal Ocean Science*

One question after an oil spill is the toxicity of thin oil sheens to early life stages of aquatic species and if that toxicity can be magnified by interaction of hydrocarbon compounds with ultraviolet (UV) light. Many early life stages congregate at the surface or in the upper mixing layer making them prone to UV light exposure and thin sheens of oil at the surface. Laboratory testing was used to assess UV-oil sheen interactions with grass shrimp (*Palaemonetes pugio*), a common estuarine species. Newly hatched grass shrimp larvae were exposed to a 1 µm thick fresh oil sheen for 24 h with or without a 6-h pulse of a UV light. Grass shrimp were then moved to clean seawater and non-UV conditions to measure development, growth, and reproductive fitness. Minimal toxicity was observed after the initial exposure but larval life cycle development was significantly delayed in shrimp exposed to the UV enhanced slick. After reaching sexual maturity, shrimp were paired to evaluate effects on reproduction. Shrimp initially exposed to the UV enhanced slick as larvae had a significant reduction in fecundity compared to controls. This demonstrates the importance of examining the interactions between UV light and oil since negative effects to aquatic organisms may be underestimated if based on standard laboratory testing with fluorescent lighting. Acute exposures of early life stages to thin oil sheens and UV light may lead to long-term impacts to individuals and ultimately to grass shrimp populations.

**443 Lipid, growth and 1st year survival impacts in Polar cod (*Boreogadus saida*) following embryonic oil exposure to Alaskan and Norwegian oil**

*B. Laurel, NOAA / Alaska Fisheries Science Center; L. Copeman, Oregon State University / CEOAS; J. Incardona, T. Linbo, N. Scholz, G.M. Ylitalo, NOAA Fisheries / Northwest Fisheries Science Center; P. Iseri, NOAA / Alaska Fisheries Science Center; T. Nordtug, SINTEF Ocean / Environmental Technology; E. Sorhus, Institute of Marine Research / Reproduction and Developmental Biology; C. Donald, Institute of Marine Research; S.E. Allan, NOAA / Office of Response and Restoration; M. Spencer, NOAA / Alaska Fisheries Science Center; J. Cameron, NOAA / Northwest Fisheries Science Center; S. Meier, Institute of Marine Research*

Recent evidence suggests that embryonic oil exposure impacts the lipid metabolism and cardiocirculatory function in marine fish. Polar cod *Boreogadus saida* may be particularly vulnerable to oil because they are an energy-rich forage species that depends on stored lipids to successfully overwinter in the Arctic. In 2017, we tested this hypothesis by exposing embryos to physically dispersed microdroplets of Alaskan oil for 3 days during cardiac organogenesis, followed by a 4-day washout period and transfer to clean water. Total polycyclic aromatic hydrocarbon dose concentrations in sea water were $0.9 \pm 0.3$, $3.3 \pm 0.4$, and $15 \pm 5$ µg/L and $63 \pm 11$, $505 \pm 105$, and $1170 \pm 170$ ng/g wet weight in embryos, respectively. Embryos were assessed for oil-induced cardiotoxicity immediately after exposure (28 dpf) and at hatch (42 dpf). Biometrics and lipid composition were determined at several points up to ~150 days post-hatch. For the 15 µg/L and 3.3 µg/L exposure concentrations, either all or most of the hatched larvae had severe craniofacial malformations. Large numbers of larvae with a normal morphology from the 0.9 µg/L exposure showed significant long-term growth impairment. There was a dose-dependent increase in triacylglycerols (TAG) and free fatty acids (FFA) in yolk sac larvae that was not present in the egg-phase but that persisted through first feeding. However, in surviving juveniles (0.9 µg/L exposure), TAG levels were reduced after flexion relative to controls. In 2018, a similar experiment was conducted using Norwegian oil in order to determine the lowest effective exposure concentration, and track bioenergetic impacts beyond 150 days post-exposure. Preliminary findings suggest that 0.3 µg/L exposure concentrations do not statistically impact growth phenotypes, but tissue analyses and respiration measures are ongoing. Collectively, these data suggest that storage and fuel lipids (TAG and FFA) are underutilized or inappropriately synthesized (or both) in exposed first-feeding larvae, while these lipids are burned excessively in juveniles rather than accumulating for overwintering. This supports an exposure and injury model in which embryonic contact with oil leads to irreversible lipid-bioenergetic deficits which in turn could underlie poor larval growth, and consequently, reduced recruitment due to high overwintering juvenile mortality.

**444 The oxidative stress response of developing zebrafish embryos exposed to hypoxia and a complex mixture of polycyclic aromatic hydrocarbons**

*C.D. Lindberg, R. Trevisan, R.T. Di Giulio, Duke University / Nicholas School of the Environment*

Estuarine and riverine ecosystems are often important nursery habitats for aquatic species. These are highly dynamic systems, often plagued with increasingly prevalent environmental stressors, such as hypoxia. They also act as sinks for anthropogenic contaminants, including polycyclic aromatic hydrocarbons (PAHs). Embryonic co-exposures to PAHs and hypoxia have been found to result in compounding toxicity in multiple fish species, although the mechanisms by which this occurs are not fully understood. Based on evidence that both hypoxia and PAH exposures induce oxidative stress in developing organisms, we hypothesized that this mechanism could play a role in the interactive toxicity seen after co-exposures. To test this, we exposed zebrafish embryos to non-teratogenic doses of a real-world complex PAH mixture with and without hypoxia beginning at 6 hpf. After 24 hours of exposure, embryos were removed from exposure conditions and were either used immediately for experimentation or placed into clean "recovery" conditions for either 1, 5, or 18 hours before sampling. Our endpoints target several facets of the oxidative stress response: pro-oxidant formation, antioxidant response, oxidative damage, and cellular signaling. We measured changes in gene expression and enzyme activity for several antioxidants including glutathione peroxidase, glutathione reductase, and catalase, utilized the *hsp70* and *epre* transgenic zebrafish lines to monitor alterations in Nrf2 signaling activity and measured non-specific ROS formation with the fluorescent probe DCF. Preliminary data suggests that PAH exposures alone result in significant inductions of glutathione reductase enzyme activity across several time points of recovery, although hypoxia exposures do not. PAH exposures with and without hypoxia also appear to induce Nrf2 activity in *epre* transgenic zebrafish. Hypoxia exposures caused a slight, but not statistically significant, increase in Nrf2 signaling in *hsp70* transgenic zebrafish. Thus far, there do not appear to be interactive effects of hypoxia and PAHs on the oxidative stress response of developing zebrafish embryos immediately after removal from exposures. Future work will focus on periods of re-oxygenation, as these are more likely to induce oxidative stress in fish species.

**445 Development of a new regulatory test method for the marine copepod *Acartia tonsa***

*P.M. Antunes, L.J. Novak, S.J. Kirkpatrick, AquaTox Testing & Consulting Inc.; R.P. Scroggins, R.R. Hennessy, L.A. Van der Vliet, Environment and Climate Change Canada / Method Development & Applications Unit, Science & Technology Branch*

A 10 year review of the Canadian Metal Mining Effluent Regulations (MMER) has recently been completed and has identified the need for a fish and invertebrate test method suitable for assessing the acute lethality of saline effluent discharged into marine or brackish environments. The freshwater invertebrate *Daphnia magna*, currently used to monitor the acute lethality of mine effluents in the MMER, is inappropriate for toxicity testing of saline effluents to be discharged to marine or estuarine environments as *D. magna* is intolerant of salinities in excess of 4 ‰. To fill this gap in regulatory testing, Environment and Climate Change Canada launched an initiative to develop a Reference Method using the marine copepod, *Acartia tonsa,* to measure the acute lethality of saline effluents. The proposed test method will be based on a 48 hr exposure starting with the egg stage, whereby newly laid eggs are obtained from breeding male and female copepods. The test endpoint will be survival, which will be expressed as hatching and mobility. Research and method development has been conducted over the last 2 years, and included: determination of the conditions needed to establish in-house cultures of *Rhodomonas salina* (an algal food source) and *A. tonsa*; reference toxicant testing with nickel chloride ($NiCl_2$); development of test methodology (including test endpoints and validity criteria) and; management of two rounds of an inter-laboratory study involving definitive tests with $NiCl_2$ and phenol to validate the proposed test method. One of the key aspects of the inter-laboratory study will be to use the data acquired to establish reasonable acceptability criteria for control organism survival (with consideration given to both % egg hatching success and % mobility). This presentation will provide an overview of some of the research conducted to date, including lessons learned and the results of both rounds of inter-laboratory testing (involving six labs across Canada).

## Exposure to Crude Oils: Linking Laboratory Endpoints to Field Observations

**446 Chemical and physical characteristics of oil in aquatic environments: Comparison of laboratory-prepared exposures to field observations**

*H. Forth, J.M. Morris, C.R. Lay, Abt Associates; J. Holmes, Stratus Consulting Inc.; C.L. Mitchelmore, University of Maryland Center for Environmental Science / Chesapeake Biological Laboratory*

As oil moves through marine and freshwater environments, a variety of physical and chemical processes can occur. These processes can impact the chemical composition and physical condition of the oil, where the oil goes, and ultimately how, and to what, aquatic organisms are exposed. Linking the potential impacts of oil spilled in the environment to laboratory-based endpoints requires understanding how oil behaves under different field conditions and relating that to the chemical and physical characteristics of the oil contaminants for different toxicity testing exposure scenarios. Through different oil spill research efforts, we have conducted extensive characterization of different toxicity testing exposure scenarios including three commonly used water-accommodated fractions (WAFs) and different oil slick preparations. We have also characterized the chemical composition and physical condition of oil slicks and dispersed oil within aquatic environments in the field. In this presentation, we will present results from our characterization of WAF and slick preparations for laboratory-based toxicity tests and discuss how they relate to our observations in the field.

**447 Contaminated Sediments are the Source of Surface Sheens in the Northern Gulf of Mexico Around the Toppled Taylor Energy Platform**

*C. Reddy, Makepeace Environmental Solutions, LLC; W. Bryant, CK Associates LLC; R. Camilli, Navistry Corporation; E. Overton, Lousiana State University*

In 2004, a production platform owned by Taylor Energy in the Mississippi Block 20 of the northern Gulf of Mexico was toppled by a mudslide during Hurricane Ivan. Fourteen years later, surface sheens continue at the site, but the source (s) and location (s) have not been fully constrained. Past activities at the site that disturbed the bottom sediments led to some of the largest relative estimates of daily releases. Hence, moving forward it is necessary to gauge the relative sources with an understanding that actions at the seafloor increase load to the environment above the sediment. The situation at MC20 differs from the norm established by many spills in that approximately 20 different wells (endmembers or "source" oils) were released into local bottom sediments, the water column, and the sea surface. Sheens are still observed even after well interventions were completed in 2011. Potential source(s) and location(s) on the seafloor were identified after two major field studies in 2012/2013. Two distinct zones of heavily contaminated sediment exist on the seafloor at the excavated former well-bay area and near the toppled jacket, approximately 600 feet downslope. Other locations sampled at the same time, even within six meters from these heavily contaminated sites, had much lower concentrations of total petroleum hydrocarbons and distinct chemical "fingerprints". In 2017, over a six-week period, we collected ~60 surface sheen on 10 separate days that were also geospatially and geophysically time-stamped (ocean currents and sonar). We analyzed these samples for biomarker ratios and used cluster analysis to compare them to our historical database and each 2017 sample. Overall, the 2017 surface sheens are heterogeneous, do not appear to be from a single oil, and have the greatest similarity to samples from the highly contaminated chemically heterogeneous sediments near the toppled jacket. We argue that surface sheens are from remnant (released prior to well interventions) oil that rises out of the contaminated sediments and the varying locations of surfacing oil droplets causing the sheens is driven by currents. In addition, an erosion pit is located at the main release area. A mass-balance-based approach further supports this finding and reveals that a leaking well is not supporting the sheen at all or below a detectable level. This information is critical for evaluating potential mitigation actions including natural attenuation.

**448 Using in situ bioassays to monitor freshwater post-spill conditions over 3 years in Blacktail Creek, North Dakota**

*A. Farag, USGS / CERC / Jackson Field Research Station; D. Harper, USGS / Columbia Environmental Research Center; I. Cozarrelli, USGS / Earth System Processes Division, Water Mission Area*

In situ and site water bioassays are an important tool to directly assess the ability of resident species to survive in post-spill environments. These experiments, while potentially labor intensive, are relatively short (96 h) and require minimal technology to perform. While this seems to be an uncomplicated approach, the interpretation of results in an uncontrolled field situation can quickly become more complicated. Determinations of cause and effect for observed mortalities are improved when in situ bioassay data are coupled with extensive organic and inorganic post-spill geochemistry data from identical sites at similar times. We monitored the survival of fathead minnow (a resident species), in Blacktail Creek, Montana at low flow for three years 2015 – 2017 following a 2014 wastewater-pipeline rupture and oil spill. During the first two years we performed in situ bioassays and during 2017, we used site water collected from multiple sites to conduct 96 h laboratory experiments. Four experimental sites ranged from 0.9 km upstream of the spill to 22.9 km downstream from the spill. Extensive mortality was documented at only the site 7.2 km downstream from the spill during 2015. Geochemistry data collected on Day 0 defined a signature likely from the spill products at the same site including elevated trace hydrocarbons, and a Sr isotope ratio reflective of the pipeline fluid. An oil-sheen was observed at the 7.2 km site at 72 h and two dead resident fish were also observed at this site only. At 96 h, 2.5% survival was observed in the experimental chambers at the 7.2 km site. Reduced temperatures and increased Cl (up to 568 mg/L) and $HCO_3$ (up to 727 mg $CaCO_3$/L) concentrations suggest a pulsed upwelling of groundwater into the stream at the time that mortalities were observed. Chemistry data also suggest that the deaths were most likely attributable to elevated ammonia (calculated from measured pH and ammonium concentrations of 3.4 mg N/L) released from groundwater upwelling apparently connected to the spill. Significant mortalities, oil sheens, and elevated ammonia were not documented during 2016 or 2017. While a chemical signature of the spill was still possibly present, it was less than in previous years. The question remains about whether the 96 h in situ or site water experiments conducted annually are sufficiently timely to observe any episodic ammonia fluxes into the river, or aquatic-health impacts, if they are still occurring.

**449 A laboratory based evaluation of biomarker selection used to monitor post-spill light crude oil exposure in fish**

*J. Baker, M. Gagnon, Curtin University / School of Molecular and Life Sciences*

One of Australia's worst oil spills occurred in August 2009, following a well blow out on a drill platform located 260 km off the northwest coast of Australia. An estimated 23.5 million L of light crude oil and condensate were spilled in to the offshore marine environment over 74 days before the oil release was successfully capped. Scientific monitoring of crude oil exposure in fish began immediately following the cessation of the oil release and were undertaken for 2 years post-spill. Research focussed on the use of liver detoxification enzymes (through ethoxyresorufin-*O*-deethylase activity of hepatic microsomes, EROD activity), biliary polycyclic aromatic hydrocarbon (PAH) metabolites, sorbitol dehydrogenase (SDH activity) and DNA damage (8-oxo-dG quantification) as biochemical markers to monitor crude oil exposure in captured fish. Results showed limited differences between oil impacted and non-impacted sites at any stage post-spill. Questions have therefore been raised regarding the suitability of these biomarkers for monitoring exposure to light crude oil, of which is compositionally very different to that of a heavy crude oil. A lack of higher molecular weight PAHs in light Western Australian crude oils, which are known to be responsible for inducing a response in many of the selected biomarkers, may be the reason for the lack of differences in the post-spill monitoring results. The current research aimed to test the biomarkers used in the aforementioned oil spill in a controlled laboratory setting. Fish (*Lates calcarifer*) were exposed to the water accommodated fraction (WAF) of light crude oil for a period of 7 & 14 days, with additional fish depurated for another 7 & 14 days, followed by analysis of the biomarkers used during the oil spill monitoring program. Results showed no response for EROD activity, SDH activity or DNA damage for any time period or concentration levels. PAH bile metabolites were a sensitive biomarker of exposure with a clear dose and time response. Findings highlight the need for the development of a range of sensitive biomarkers in fish, suitable for light crude oil exposure with many 'traditional' monitoring tools not the most appropriate selection for this type of exposure. The employment of these traditional biomarkers in a light crude oil spill scenario may lead to false impressions on the severity of impacts on the marine environment.

**450 Comparing transcriptional profiles of lab exposed and field collected flounder following the Deepwater Horizon incident**

*R.J. Griffitt, University of Southern Mississippi / Coastal Sciences; D. Wetzel, Mote Marine Laboratory / ELF; R. Takeshita, National Marine Mammal Foundation*

The use of large scale whole genome or transcriptome profiling techniques to assess subtle effects of contaminant exposure in aquatic or marine organisms has become standard. In the aftermath of the 2010 Deepwater Horizon oil spill, many research groups used microarrays or RNAseq to identify genes or pathways that were affected by oil exposure, research which lead to many valuable insights about the interaction between organisms and exposure history. Often these are based on controlled laboratory exposures, which allow researchers to tightly constrain the experimental setup, and to ascribe the resulting transcriptional changes to the exposure with some degree of history. Transcriptional profiling using field collected organisms is significantly more challenging to perform and interpret with any degree of certainty, due to the lack of ability to control the dose or environmental factors that may affect the response. When possible, comparing the results obtained from lab exposed animals to field collected individuals is a powerful way to validate the in-lab data, and identify the responses that are ecologically meaningful. We conducted three experiments where flounder were exposed to oil contaminated sediment and liver transcriptional profiles were assessed. One experiment was based on clean sediment that was contaminated with oil, the second with sediment collected from the field with preexisting levels of oil contamination, and the third was a collection of flounder from various sites in the Gulf of Mexico with differing levels of historical oil contamination. Using IPA, we compared the transcriptional profiles of the oi-exposed flounder from the different experiments. The results indicate that there is a degree of overlap in the genes and pathways that were identified as affected among the different analyses and demonstrate that laboratory exposures provide useful information about field events.

**451 Impacts of oil exposure in early and later life stages of marine fish**

*M. Grosell, J.D. Stieglitz, R.M. Heuer, University of Miami / Marine Biology and Ecology; C. Pasparakis, University of Miami; L. Schlenker, RSMAS, University of Miami / Marine Biology and Ecology; J.T. Magnuson, University of California, Riverside / Environmental Sciences; D. Nelson, University of North Texas; G. Xu, McGill University / Department of Environmental Sciences; D. Schlenk, University of California, Riverside / Department of Environmental Sciences; D.A. Crossley, University of North Texas / Department of Biological Sciences; A.P. Roberts, University of North Texas / Advanced Environmental Research Institute; D.D. Benetti, RSMAS University of Miami / Department of Marine Ecosystems and Society*

Impacts on cardiac function and development in early life stage fish are commonly reported effects of crude oil toxicity. Such impacts include pericardial edema and reduced stroke volume and cardiac output. However, additional sensitive endpoints in early life stages include accelerated metabolic rate, accelerated yolk sac depletion, and alterations of buoyancy in developing embryos. Furthermore, brief exposures during embryonic development lead to reduced swim performance and reduced visual acuity in later stage juveniles. Oil exposure results in altered olfactory responses, reduced prey capture ability, and higher susceptibility to predation, in juvenile fish, likely due to altered central nervous system function. Brief, low-level oil exposures, also impacts adult fish leading to reduced aerobic scope and swim performance. The lower swim performance in adult oil-exposed fish, is due to reduced cardiac output driven by reduced stroke volume. Isolated cardio-myocytes show that sarcomere shortening upon electrical stimulation is reduced by acute oil exposure which likely explains the reduced stroke volume observed in intact, oil exposed fish. Such reductions in cardiomyocyte contractility are likely related to impaired cellular calcium cycling also suggested by RNAseq data. Efforts are ongoing to examine the combined effects on sensory systems and the cardiovascular system on habitat utilization and survival in the wild. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER).

**452 Taking the laboratory to the field: Differences in migration patterns, habitat use, and spawning behavior of control and oil-exposed wild mahi-mahi**

*L. Schlenker, J.D. Stieglitz, R.H. Hoenig, E.A. Babcock, RSMAS University of Miami / Marine Biology and Ecology; R. Faillettaz, RSMAS University of Miami; C. Lam, University Of Massachusetts Boston; D.D. Benetti, M. Grosell, University of Miami / Marine Biology and Ecology*

Mahi-mahi (*Coryphaena hippurus*, "mahi" in the following) is a highly migratory ecologically and commercially important pelagic fish species that inhabit tropical and sub-tropical waters around the world. The 2010 *Deepwater Horizon* blowout released approximately five million barrels of crude oil into the northern Gulf of Mexico (GOM) and coincided spatially and temporally with the spawning window for mahi. In the laboratory, environmentally realistic oil exposures reduce cardiac performance and aerobic swimming speed of adult mahi. As a high-performance fish, the ecology of mahi is tied to their vertical dives, migrations, and spawning; all of which is poorly studied and may be affected as a result of crude oil exposure. To better understand behavior in wild mahi, we collaborated with Wildlife ComputersÔ to build pop-up satellite archival tags (PSATs) to measure acceleration, depth, temperature, and light levels (for geolocation modeling). To model acceleration patterns around spawning we tagged wild-caught captive mahi with PSATs and observed them in a

30,000 L tank for three weeks. We followed this captive-based experiment with the deployment of 16 PSATs on wild mahi in the Florida straits (n=14) and the GOM (n=2). Wild mahi tagged in the Florida straits generally migrated north and eastward moving up to 100 km per day, while mahi in the GOM remained in the GOM for the duration of the tagging period. Overall, mahi inhabited water temperatures between 31 and 17 °C, explored depths from the surface to 250 m, and spent more time at depth at night than during the day. Exploration of putative spawning events is ongoing. In the summer of 2018 we are conducting an experiment in the GOM where wild mahi will be exposed to concentrations of crude oil observed during the 2010 spill for 24-hours onboard our research vessel, tagged with PSATs, and released into the wild along with tagged control mahi. The spawning, migration, and habitat utilization information from these PSATs will be a vital component of understanding the ecology of mahi and will also provide important information about the fate and performance of mahi exposed to oil in the wild. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in Fish for Validation of Ecological Risk (RECOVER).

**453 Ecotoxicology of Deep Ocean Spills**

*A.C. Bejarano, Research Planning Inc. / Department of Environmental Health Sciences; S. Chiasson, Loyola University / EEB; M.G. Barron, USEPA / Gulf Ecology Division*

Central issues in understanding the risks of subsea oil spills include the unknown sensitivity of deep ocean species, and the complexity and diversity of habitats that may be affected in subsea, offshore, and inshore environments. Unique aspects of the deep ocean relevant to hydrocarbon species sensitivity include the physical environment (cold temperature, hypersaline, no light, high pressure), and biological communities of unknown sensitivity, including deep sea corals and vent communities. Subsea spills entering the photic zone may affect pelagic species and neuston, and result in surface oiling of sea birds, turtles and marine mammals. Risks to pelagic species will vary seasonally with the presence of sensitive life stages in the water column and sea surface. Potentially affected nearshore environments include coastal wetlands, beaches, and estuaries. Relatively little is known about petroleum toxicity to deep ocean species, as well as the diversity and interactions of species in offshore and inshore environments. Approaches for understanding species sensitivity and extrapolating toxicity to aquatic communities include species sensitivity distributions, existing toxicity databases (i.e., the chemical aquatic fate and effects database), and predictive modeling tools (i.e., interspecies correlation estimation models). This presentation will summarize the limitations, uncertainties and assumptions of toxicity estimation approaches, lessons learned from the Deepwater Horizon spill, and the role of ecotoxicology science in informing future response decisions/field assessments.

## Improving Approaches to Assess Risks to Threatened and Endangered Species from Chemical Exposure

**454 Use Versus Usage: A Critical Consideration for Modeling Pesticide Exposure to Federally Listed Threatened and Endangered Species**

*T. Hawkes, National Marine Fisheries Service / Office of Protect Resources; R.J. DeWitt, The Evergreen State College / Office of Protected Resources Endangered Species Division; S.A. Hecht, NOAA / National Marine Fisheries Service; T. Hooper, NOAA – NMFS*

Section 7 of the Endangered Species Act requires federal agencies to insure that any action they authorize, fund, or carry out is not likely to jeopardize the continued existence of any endangered or threatened species. EPA's authorization of pesticide use through its approval of FIFRA pesticide labels is a federal action subject to Section 7 consultation requirements. Should assessment of potential effects to listed species be based on the action authorized by EPA ("pesticide use" as allowed by the product labeling), or should the assessment be based on projected future use of pesticide products based on recent "pesticide usage?" This presentation will compare and contrast the two approaches for a federally-listed California Central Valley species and discuss the relevant considerations of conducting the assessment in the context of a Section 7 consultation.

**455 A refined endangered species risk assessment for aquatic species exposed to malathion**

*S. Teed, Intrinsik Corp; M.F. Winchell, Stone Environmental, Inc. / Environmental Systems Modeling; S.I. Rodney, Intrinsik Corp. / Biology; L. Padilla, Stone Environmental, Inc.; H. Rathjens, Stone Environmental, Inc. / Environmental Systems Modeling; C. Priest, Intrinsik Ltd. / Biology; P. Whatling, FMC Corporation*

The Environmental Protection Agency (EPA) and Fish and Wildlife Service (FWS) and National Marine Fisheries Service (NMFS) (the Services) are close to completing an organophosphate case study for malathion. The case study currently consists of an EPA generated biological evaluation (BE) and a NMFS biological opinion (BiOp) that was based on the results of the EPA BE. The NMFS BiOp puts forth jeopardy determinations for 12 listed species (38 distinct ecologically significant units or distinct population segments), and 38 critical habitats under their jurisdiction. Both the EPA BE and hence the NMFS BiOp for malathion did not move past a simple, highly-conservative screening-level approaches to characterizing risk. In this presentation we will discuss a refined approach to determining risk for aquatic listed species occupying both static and flowing habitat. To generate refined effects metrics, laboratory studies were evaluated for relevance and study quality and data deemed acceptable or supplemental were used to generate taxon-specific concentration-response curves and species sensitivity distributions. In a companion poster (Winchell et al. 2018) the associated refined exposure modeling effort is described. The refined exposure modeling takes advantage of the best nationally available spatial datasets providing the information necessary to improve the parameterization of regulatory aquatic exposure models such as the PRZM landscape and VVWM receiving water models, and thus refine exposure estimates. This exposure modeling approach resulted in species-specific EEC distributions that could be further filtered according to habitat characteristics (flow rate, water body size) and grouped according to contributing watershed characteristics. Combining refined exposure and effects distributions, informed by species life history data and habitat requirements, allow the risk characterization to quickly identify regions within a species range that are likely to experience elevated risk concerns. A weight-of-evidence approach is also described that provides important context to the risk estimates and helps inform the risk characterization conclusions.

**456 A US, field-scale, herbicide spray drift deposition and biological evaluation study: Methods and implications for risk assessment**

*D. Perkins, G. Goodwin, Waterborne Environmental, Inc.; G. Kruger, University of Nebraska Lincoln; A. Lynn, ALL Consulting; F. Abi-Akar, Waterborne Environmental Inc; R. Brain, Syngenta Crop Protection, Inc. / Environmental Safety*

Spray drift from pesticide applications is considered as a potential route of exposure in environmental risk assessment. Typically, spray drift deposition is modeled using terrestrial plant effects endpoint derived from worst-case, full rate direct spray studies, and combined in the risk assessment framework to represent extreme worst-case risk to non-target organisms. The objective of this work was to merge observed plant effects with spray drift exposure in a single study. A 40-acre field-scale, spray drift study was developed to simultaneously measure spray drift deposition, airborne interception, and potential biological effects of an herbicide under conservative drift conditions and a relatively low-drift nozzle. This study was conducted in four replications, each with a two-swath spray pattern (90 ft per swath) upwind of a deposition zone (perpendicular to wind direction), generally following the generic U.S. Environmental Protection Agency verification protocol, *Testing Pesticide Application Spray Drift Reduction Technologies for Row and Field Crops*. Within each replicate application, an array of three perpendicular sampling lines were used to measure drift deposition out to 400 ft, airborne interception out to 75 ft, and potential direct plant effects at set distances (5, 15, 25, 23, and 45 ft) from the edge of the downwind spray application . At each distance and sampling line, further replication of spray drift deposition, airborne interception, and biological effects were assessed in replicated fashion in a nested, replicated design. The timing of the herbicide application for each of the four replications targeted steady wind speeds between 8 to 12 mph. Wind direction was measured within a 30-degree angle of the downwind field orientation to ensure that spray drift would travel toward the collection area and across the furthest sampling points. Results from this study design refine effects determined in laboratory studies under worst-case exposure scenarios (i.e., direct over the top application) by addressing how terrestrial non-target plants actually experience exposure under natural conditions in the field, which can better inform risk assessment and risk management decisions.

**457 Development of a probabilistic co-occurrence analysis approach for listed insect species**

*J. Bang, Syngenta Crop Protection / Environmental Safety; L. Richardson, K. Budreski, Stone Environmental, Inc.; M.F. Winchell, Stone Environmental, Inc. / Environmental Systems Modeling; M. Feken, Syngenta / Ecological Risk Assessment; R. Brain, Syngenta Crop Protection, Inc. / Environmental Safety*

Defining species distribution as well as pesticide use areas is an important step in understanding potential co-occurrence of listed species and their critical habitats and pesticide use areas. Development of scientifically rigorous approaches to better understand the likelihood of proximal overlap between pesticide application and listed species habitat can improve such efforts. Here we demonstrate a new method of co-occurrence analysis that combines spatial models of pesticide use areas and species distribution in a probabilistic framework. Specifically, we evaluated three components: 1) advance our previously published probabilistic crop footprint methodology (Budreski et al., 2016), 2) develop a habitat modeling approach for listed insect species, and 3) develop a joint probabilistic co-occurrence analysis approach using advanced species and use area data. Using the principles of the Bayes' Theorem, probabilistic spatial models of pesticide use areas were constructed by integrating information from the Cropland Data Layers, National Land Cover Datasets, NASS Census of Agriculture and Quick Stats and all classification accuracy assessments. In addition, we incorporated available pesticide use data (USGS) as well as recent satellite imagery products to improve field boundary delineation. To develop and validate a probabilistic species distribution model, we tested multiple methods by identifying species-specific landscape variables that could serve as predictors for listed species with different life histories and habitat needs. We also parameterized these models with novel predictor variables including newly available remote sensing data products. We tested best-fit distribution models using the available observation records for the species. Combining two refined modeling outputs, we conducted the joint probabilistic co-occurrence analysis by integrating crop presence probability and likelihood of habitat suitability. This work serves as a framework to enhance the accuracy and efficiency of threatened and endangered species assessments using a data-driven likelihood analysis of species co-occurrence.

**458 Developing Integral Projection Models for Aquatic Ecotoxicology**

*N. Pollesch, M. Etterson, S. Kadlec, K. Flynn, USEPA / ORD / NHEERL Mid-Continent Ecology Division*

Extrapolating laboratory measured effects of chemicals to ecologically relevant scales is a fundamental challenge in ecotoxicology. Structured population modeling seeks to utilize data and dynamics linked to a given trait (or traits) of individuals in the population; age-, stage-, and size-structured modeling approaches are common examples. We present integral projection models as a novel and promising approach to structured population modeling within an ecotoxicological context. We demonstrate the flexibility of this approach to integrate chemical and non-chemical stressors into complicated life-histories by showing how our approach can be adapted to accommodate batch-spawning, over-winter survival, and the effects of time-variable exposure scenarios in Fathead minnow (*Pimephales promelas).* We also discuss how this approach can be adapted to inform the ecological risk assessment of the endangered Delta smelt (*Hypomesus transpacificus*), by incorporating semelparity and spatially distinct metapopulations for different life-stages.

**459 Development of a neurobehavior adverse outcome pathway in larval fish to facilitate cross-species extrapolations**

*C.A. Murphy, Michigan State University / Department of Fisheries and Wildlife; M.J. Carvan, University of Wisconsin-Milwaukee / School of Freshwater Sciences; N. Vinas, US Army / Engineer Research and Development Center; L. Ivan, J. Albers, M. Jones, Michigan State University / Department of Fisheries and Wildlife*

To assess the impacts of chemical exposure on threatened or endangered species usually requires making assumptions about animals where there is limited information on which to base risk assessment. Our lab is developing methods to improve cross-species extrapolations so that we can make decisions on data poor species. We report on progress for an approach that we believe has the potential to improve cross-species extrapolations and to bridge essential data gaps so that we can predict effects from molecular/cellular level to population and community level responses on endangered species from experiments conducted on laboratory animals. We found that the adverse outcome pathway (AOP) framework is a highly useful organizing base from which to collect data in a systematic way to facilitate cross- species extrapolations. We are developing a neurobehavior AOP in the zebrafish and we are extrapolating it to two other species of ecological importance, the fathead minnow and the yellow perch. We collected in depth data on yellow perch and fathead minnow that may allow us to predict from molecular initiating evens to cohort survival and growth which are endpoints that are critical for ecological risk assessments. With these data sets we will be able to assess the feasibility of cross-species extrapolations – we will be able to determine what information is useful for cross-species comparisons and what information is lost when a model species is used instead of the target organism and the amount of error associated with cross-species assumptions.

**460 Using plant functional traits to guide herbicide risk assessments**

*P. Rueda-Cediel, University of Minnesota / Ecology, Evolution and Behavior; R. Brain, Syngenta Crop Protection, Inc. / Environmental Safety; A. Schmolke, Waterborne Environmental, Inc. / College of Biological Sciences; N. Galic, Syngenta Crop Protection, LLC / Environmental Safety; V. Forbes, University of Minnesota / Ecology, Evolution & Behavior*

Plant functional traits are morpho-physio-phenological traits, which influence fitness indirectly via their effects on growth, reproduction and survival. This makes functional traits very important because they determine how plants will respond to external factors and potentially how a population will respond. Functional traits have been successfully linked with demographic traits for neotropical trees, shrubs, palms and herbaceous plants. There are well-supported relationships between particular functional traits and demographic indices. The present study sought to address two points relevant for risk assessment of threatened and endangered (listed) plants; First, it expands on the available plant functional traits-demography links by identifying functional traits for listed species using demographic and eco-physiological plant databases (COMPADRE and TRY) and literature. This facilitates characterization of functional traits for listed species and generates demographic data that can facilitate conservation management efforts. The second point relates to the use of plant trait characterization to enhance herbicide risk assessments for listed plant species. Surrogate plant test species, which are used to develop toxicological endpoints in risk assessments, can be incorporated in the functional trait characterization in order to provide guidance on which surrogate species to use when developing listed plant risk assessments.

Trait analyses can also inform explorations into the use of new or more reliable surrogates. The main goals of this project are to identify data gaps for listed plant species, which are usually limited on demographic data, and to attempt to “fill them” once identified. This will provide useful data for the development of listed plant risk assessments at the population level.

**461 Combining an individual-based model and an aquatic food web-ecosystem model to assess ecological risks: A case study with the endangered Topeka shiner**

*S.M. Bartell, Cardno Entrix; A. Schmolke, Waterborne Environmental, Inc. / College of Biological Sciences; C. Roy, Waterborne Environmental, Inc; N. Ralston, Sage Green NRG / Earth Systems Science and Policy; D. Perkins, Waterborne Environmental, Inc.; N. Galic, R. Brain, Syngenta Crop Protection, Inc. / Environmental Safety*

The Comprehensive Aquatic System Model (CASM) is a process-based integrated bioenergetics and habitat quality model that simulates population, community, and ecosystem-level effects of chemical stressors based on an aggregated population structure defined by an average-sized individual. An individual-based bioenergetics and population model (IBM) was developed for the endangered Topeka shiner (*Notropis topeka*) to incorporate detailed life-history and age-specific and size-specific attributes of population dynamics not represented in the CASM. The models were executed in tandem with daily IBM population growth dynamics transferred to CASM, which in turn computed the corresponding daily modifications to the food web. The CASM food web results were transferred back to the IBM in the form of adjusted Topeka shiner prey biomass values. This uniquely integrated model combination was implemented to simulate potential ecological risks for Topeka shiner in a generalized Iowa headwater pool, representative of known Midwestern habitat and range for this species. Ecological risks were computed using time-integrated differences between the population biomass values of 365-day baseline and exposure simulations. Risks were estimated for example daily pesticide exposures of varying magnitude, timing, and duration. Potential direct toxic effects to Topeka shiners were modelled within the IBM. The resulting modelled impacts on population biomass were used by the CASM to compute corresponding food web-ecosystem effects. The IBM provided the capability to examine the potential population-level risks based on detailed sensitivities of early life stages and adults to pesticide exposures. The CASM extended the IBM assessment capability by extrapolating potential direct effects on Topeka shiners to associated indirect changes in headwater pool community structure and ecosystem function. The presentation highlights the advantages afforded by the integrated IBM-CASM modeling approach to ecological risk assessment.

## Evolutionary Ecotoxicology Then and Now: Decades of Progress in the Science of Evolution to Pollutants

**462 The contribution of detoxification pathways to pyrethroid resistance in *Hyalella azteca***

*C. Fung, Southern Illinois University Carbondale / Zoology Fisheries; D.P. Weston, University of California / Department of Integrative Biology; K.M. Major, H.C. Poynton, University Of Massachusetts Boston / School for the Environment; M.J. Lydy, Southern Illinois University-Carbondale / Center for Fisheries Aquaculture and Aquatic Sciences*

Chronic exposure to pyrethroids can result in sublethal impacts to non-target species in aquatic systems, driving population-level changes. Characterizing the underlying mechanisms of resistance is essential to better understanding the role and potential consequences of contaminant-driven microevolution. The current study demonstrates that multiple mechanisms enhance the overall phenotypic expression of resistance characteristics in *Hyalella azteca*. In VGSC mutated *H. azteca*, both adaptation and acclimation traits may have a role in the attenuation of the adverse effects to pyrethroid exposures. Pyrethroid resistance is primarily attributed to the heritable mutation at various loci of the voltage-gated sodium channel, resulting in reduced target-site sensitivity. However, some additional reduced pyrethroid sensitivity can also be conferred through reversible physiological responses to environmental conditions, such as enhanced enzyme-mediated detoxification. Two pathways significantly contributed to detoxification of permethrin in *H. azteca,* including cytochrome p450 monoxygenases (CYP450) and general esterases (GE). Over time, VGSC mutated *H. azteca* retained most of their pyrethroid resistance, though there was some increased sensitivity from parent to offspring when reared in the absence of stressors. The permethrin 96 h LC50 declined from 1809 ng/L in P0 individuals to 1123 ng/L in the F1 generation, though still remained well above the 20.4 ng/L of wild-type individuals. This reduction in tolerance was likely related to alterations in acclimation mechanisms conferring resistance traits, rather than changes to target-site sensitivity. Enzyme bioassays indicated decreased enzyme activity from P0 to F1, whereas the VGSC mutation was retained. The permethrin LC50 values in resistant *H. azteca* were still two orders-of-magnitude higher than non-resistant populations indicating that the largest proportion of resistance was maintained through the inherited VGSC mutation. Thus, some variation in phenotypic expression of resistance characteristics in *H. azteca* over time is likely associated with uninheritable genetic factors or non-constitutively expressed traits controlling enzyme pathways which overlie a strong heritable component of resistance. A better understanding of the mechanistic and genomic basis of variable acclimation will be necessary for better predicting the ecological and evolutionarily consequences of contaminant-driven change in *H. azteca*.

**463 Contaminant-Mediated Selection Alters Gene Flow and Genetic Diversity in Mussels from the Strait of Istanbul**

*C.W. Theodorakis, Southern Illinois University Edwardsville / Department of Enviromental Sciences; M.A. Meyer, Southern Illinois University Edwardsville / Department of Biological Sciences; K. Schramm, Helmholtz Zentrum Munchen / Molecular EXposomics; O. Okay, Istanbul Technical University / Faculty of Naval Architecture and Ocean Engineering*

Mediterranean mussels (*Mytilus galloprovencialis*) were collected from various sites along the Strait of Istanbul in Turkey. These sites have been the focus of a long-term environmental and biomonitoring project, and the sediment concentrations of polycyclic aromatic hydrocarbons, metals, pesticides, and polychlorinated biphenyls at these sites have been previously characterized. DNA was extracted from these mussels, and a 562 bp-long segment of the mitochondrial control region was amplified by PCR, sequenced, and subjected to various genetic and phylogenetic analyses. The major findings were that 1) a minimum spanning tree identified 3 clades (Clade 1, Clade 2, Clade 3; Clade 3 contained only a single rare haplotype) separated by the nearest clade at least 15 mutational steps, 2) the amount of genetic diversity and frequency of Clade 1 haplotypes was negatively correlated with degree of sediment contamination, while the frequency of Clade 2 haplotypes was positively correlated with the level of environmental contamination, 3) Tajima’s D test indicated that there was balancing selection at the least contaminated site, and purifying selection at the most contaminated site, 4) $\Phi_{ST}$ values and genetic structuring among sites corresponded to levels of contamination. It was concluded that 1) a Pleistocene vicariance event produced the clades, which may differ in tolerance to toxicants, 2) strong directional currents and local selection can produce fine-scaled genetic structure in this species, 3) the was evidence that toxicant susceptibility was associated with D-loop haplotypes, and this affected levels of genetic diversity and gene flow. This study suggests that evolutionary history (e.g. vicariance) may affect differential responses to toxicants among individuals within populations, and this should be taken into consideration in ecotoxicological studies.

**464 Variation in signatures of cadmium-induced mitochondrial DNA mutations in Daphnia pulex reveal evolutionary effects of pollution**

*T. Leuthner, Duke University / Integrated Toxicology and Environmental Health; N. Keith, Indiana University Bloomington / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; C. Jackson, Indiana University / The School of Public and Environmental Affairs; S. Glaholt, Indiana University / School of Public and Environmental Affairs; J.N. Meyer, Duke University / Nicholas School of the Environment; J. Shaw, Indiana University / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics*

Understanding the origin, persistence, and consequences of mitochondrial DNA (mtDNA) mutations are increasingly fascinating as recent evidence implicates heritable mtDNA mutations in population level phenotypes as well as organismal health. However, the effect of chemical stressors on mtDNA mutation rates is largely unknown. We use an experimental evolution approach in the freshwater crustacean, *Daphnia pulex*, to investigate variation in germline mtDNA mutation rates of two different populations: one population from a mining-devastated region, and the other from a pristine environment. The genotype from the contaminated region is from an adapted population of *D. pulex* that is tolerant to cadmium (Cd) after a century of exposure to iron ore smelting runoff. We take advantage of this variation in population histories to investigate the effect of Cd on mutation rate, which is a known mutagen. Twelve genetically identical individuals of the tolerant ("T") population and a Cd-sensitive reference population ("S") of D. pulex were exposed to both control, and chronic, environmentally-relevant cadmium conditions for almost 2,000 generations via a mutation accumulation (MA) experiment, followed by deep-coverage, whole-generation sequencing. There is no effect of population history or Cd on overall mitochondrial genome mutation rates. However, there is a trend towards suppression of C:G > A:T transversion mutations and both A:T > G:C and C:G > A:T transition mutations in the "T" MA experimental lines. Strikingly, there are specific context-dependent mutations that occur at C/G sites in the "S" experimental lines, which are absent in the "T" MA experimental lines. We also observe variation in the frequency and region of insertion and deletion mutations, with "T" indels occurring more randomly throughout the genome, with "S" indels occurring at high frequency in the D-loop, or non-coding region, of the mitochondria. Overall, we see low frequencies of mutations, ranging from 3 – 50%, which suggests that either mutations are recent, or that *D. pulex* retain low levels of heteroplasmy. One line of "S" in Cd shows a mutator phenotype, with a mutation rate >100-fold higher than the other experiments, which to our knowledge has not been observed in a mitochondrial genome. Overall, these results suggest variation in the spectrum of mtDNA mutations across different populations under variable environments.

**465 Evolutionary toxicology in practice: Case studies with Daphnia highlight potential regulatory applications**

*J. Shaw, Indiana University / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; R. Keith, Indiana Universtity / School of Public and Environmental Affairs; C. Jackson, S. Glaholt, Indiana University / School of Public and Environmental Affairs; J. Colbourne, University of Birmingham / School of Biosciences*

Differences in inter-individual response are described by variation in environments and genomes that combine to give rise to phenotypic variation observed in populations. Evolutionary toxicology provides tools for understanding these features that offer links to phenotypes, which are in-line with proposed changes in regulatory toxicology. This talk will draw from laboratory and field investigations, which include long-term mutation accumulation experiments and environmental genomic case studies, to explore how environmental stress contributes to genome variability, influences the fate of genetic variation in populations, and over micro-evolutionary time scales determines the fate of phenotypes. These studies contribute to and make use of maturing genomic tool kits for the water flea, *Daphnia pulicaria*, including new reference genomes. Using this animal model, we explore how stress shifts the genome distribution of mutations and changes the rate of specific mutational classes –including those that alter epigenetic state. We discuss how genome variation drives functional variation in gene expression and gene regulatory networks, and contributes to organismal fitness. We explore how environment-induced alterations in the magnitude and distribution of mutations, including gene copy number variation (CNV), in natural populations contributes to adaptations to extreme environments. These findings, which demonstrate the importance of understanding genome variation and the evolutionary forces that shape it, provide answers that can help fill regulatory needs. The field provides tools for identifying molecular pathways that contribute to adverse outcomes and predicting the fate of populations. After decades of research these tools are catching pace with the complexity of the problems, however, their output has not been directed towards meeting regulatory needs. Perhaps, it is time to move the discussion from evolutionary toxicology as an academic pursuit to its role in protecting human health and the environment.

**466 Evaluating wastewater effluent exposure in wild fishes using insights from laboratory and wild populations**

*D. Winkelman, J.R. Anderson, Colorado State University / Fish, Wildlife and Conservation Biology; A.M. Vajda, University of Colorado Denver / Integrative Biology; A. Jastrow, USEPA / Region 5*

Complex chemical mixtures in effluents below municipal wastewater treatment plants (WWTPs) are difficult to assess and their effects on organisms are poorly understood. In the South Platte River basin in Colorado, estrogenic impacts from treated municipal wastewater have been observed, but there is limited data about the consequences of estrogen exposure for wild organisms. Our goal was to evaluate several species of wild fish for evidence of estrogen exposure and to determine if the effects observed in laboratory raised Fathead Minnow (FHM, *Pimephales promelas*) caged in wastewater were similar to those observed in wild fish populations. To accomplish this goal, we placed ten laboratory raised male FHM in cages both upstream and downstream of a WWTP effluent for one week, and then euthanized them, and extracted their livers for Vitellogenin (VTG) analyses. The presence of VTG is a common biomarker for estrogen exposure in male fish, and VTG presence was determined using qPCR. We also captured wild fish species (*Catostomus commersonii*, *Rhinichthys cataractae*, and FHM) at the WWTPs where we caged FHM, and measured VTG protein in wild fish blood plasma using ELISA. Finally, we caged wild FHM at the same locations in which we caged laboratory raised FHM and measured VTG production. Analysis for wild fish VTG data is ongoing, but our initial results indicate that wild FHM captured at the caging sites did not express similar levels of VTG as their caged laboratory raised counterparts. Additionally, caged wild FHM expressed more VTG than unconfined wild FHM, but less VTG than the laboratory raised FHM caged at the same spot downstream of the WWTP effluent. Our results indicate that the response of VTG production in laboratory raised FHM is more sensitive to estrogen exposure than VTG production in wild FHM, demonstrating that wild FHM seem to be acclimated or adapted to living in WWTP effluent compared to the naïve laboratory population. These results have consequences for the potential inferences being made between laboratory and wild populations and indicates that more research needs to be done to understand the differences between wild and laboratory raised populations.

**467 Genetic Architecture of Pollution Resistance in Multiple Populations of Killifish**

*J.T. Miller, University of California, Davis / Pharmacology and Toxicology Graduate Group; B. Clark, Atlantic Ecology Division / USEPA / Environmental Effects Research Laboratory; D. Champlin, D.E. Nacci, USEPA / Atlantic Ecology Division; A. Whitehead, University of California Davis / Environmental Toxicology*

Multiple populations of Atlantic Killifish (*Fundulus heteroclitus)* that reside in heavily polluted habitats along the Atlantic coast of North

America have repeatedly and rapidly evolved resistance to highly toxic dioxin-like pollutants (DLCs), which act through the aryl hydrocarbon receptor (AHR) signaling pathway. A multi-population genome-wide scan showed that wild DLC-resistant killifish populations have some shared and some unique genomic regions under selection. These studies and others suggest that resistance to the toxic effects of DLCs, such as cardiovascular and other developmental deformities, is extreme but not identical in resistant killifish populations. Here, we extended the QTL (Quantitative-Trait Locus) approach to four resistant killifish populations distributed from Massachusetts to Virginia, and employed high-density QTL interval mapping to compare and contrast genetic regions associated with DLC resistance in these diverse populations. Our results show that in all four populations, a common genomic region associates with DLC resistance. This region includes two AHR pathway genes (AHR1b/2b) that did not show obvious signatures of selection in population genome scan data. Conversely, another AHR pathway gene (AIP) falls in a genomic region showing strong signatures of selection and associates with resistance in three of the four of our mapping populations. These results also suggest that variation in AHR1b/2b may have evolved by soft sweeps on standing genetic variation in resistant populations, which are difficult to detect by traditional selection scan methods. These results also suggest that AIP is an important component in the evolutionary response to complex, heavily contaminated environments. Our findings, integrated with population genomic scans for selection, reveal the unique evolutionary trajectories that led to evolved DLC resistance in wild killifish.

**468 Metabolic tradeoffs of pollution adaptation in teleost Fish Fundulus heteroclitus**

*N. Jayasundara, Universiy of Maine / School of Marine Sciences; R.T. Di Giulio, Duke University / Nicholas School of the Environment*

Anthropogenic stressors, including chemical pollutants, are key evolutionary drivers in the environment. However, adaptive changes in fundamental physiological processes in response to anthropogenic selection pressures may have significant consequences (e.g., energy metabolic tradeoffs), but remain poorly characterized. Atlantic killifish in the Elizabeth River, Virginia have evolved resistance to a ubiquitous class of pollutants, polycyclic aromatic hydrocarbons (PAHs), and provide a unique “natural-experiment” to examine metabolic tradeoffs of rapid evolution to anthropogenic pollution. Here we focused on our ongoing and published studies and examined data from population genomics analyses, genome-wide methylation analyses, gut microbiome studies, metabolomics studies and whole organismal and developmental bioenergetics assays to determine shifts in energy metabolic processes in PAH-resistant fish. Metabolic phenotype of PAH-resistant fish is compared to fish from a clean site (Kings Creek- KC). Genomic data indicate that genes associated with cellular energy metabolism, especially mitochondrial function, are likely under selection in fish from PAH-contaminated sites. Physiological studies reveal that mitochondrial function is altered in adult tissues and in developing embryos in PAH-resistant fish. In particular, organismal and embryonic metabolic rates are higher in PAH-resistant fish compared to KC fish. However, despite elevated mitochondrial oxygen consumption rates, metabolomics data show overall suppression of metabolic products including amino acids and sugars, suggesting reduced metabolic turnover. In addition, shifts in sphingolipid metabolite levels as well as the reduced levels of sphingolipid producing bacteria in the PAH-resistant fish gut. These observations parallel the population genomic data showing that genes associated with fatty acid metabolism, including sphingolipid metabolism are under selection. Collectively, our studies demonstrate that pollution adaption and inhabiting contaminated environments may compromise energy metabolic processes in *Fundulus heteroclitus,* and these changes in energy metabolism are likely to be associated with shifts in the gut microbial community.

**469 Adaptive introgression enables evolutionary rescue from extreme environmental pollution in Gulf killifish**

*E.M. Oziolor, University of California, Davis / Environmental Toxicology; N. Reid, University of Connecticut; S. Guberman, Baylor University / Environmental Science; J. Shaw, Indiana University / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; K. Lee, S. Yair, G. Coop, University of Califorina, Davis / Center for Population Biology; A. Whitehead, University of California, Davis / Environmental Toxicology; C.W. Matson, Baylor University / Environmental Science*

Anthropogenic contamination associated with industrial activity is a widespread and active threat to the stability of populations. The Houston Ship Channel (HSC) is one example of a heavily impacted environment, where industrial activity has contributed to extreme levels of pollution, including polychlorinated dibenzo-*p*-dioxins and furans (PCDD/Fs), polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs). This study explores the impacts of chronic multi-generational exposure to industrial pollution on the physiology, demography and population genomics in a keystone coastal species – Gulf killifish (*Fundulus grandis*). We have characterized population-wide sensitivity to contaminants in fish from 12 locations across Galveston Bay, as well as the contamination levels at those sites. We found a gradient of chemical resistance that was positively correlated with contaminant concentrations. This resistance was also correlated with a suppression of the aryl hydrocarbon receptor (AHR) signaling pathway, as estimated via the activity of a down-stream regulated enzyme – cytochrome P450 1A (CYP1A). We showed that the heritability of this resistance is biparental and multi-generational. Finally, we performed full genome resequencing of many individuals from each of seven populations along this gradient of resistance and discovered that genomic regions under selection in adapted populations included several genes that regulate the AHR pathway. In addition, some of the adaptive variants in resistant *F. grandis* have been acquired through introgression of DNA from southern populations of *F. heteroclitus* within the last 50 years. To our knowledge, this represents the first case of evolutionary rescue from anthropogenic contamination through adaptive introgression and suggests that introduction of non-native species may sometimes deliver genetic variation that enables adaptation of native species to rapidly changing environments.

## Alternative Animal Ecotoxicity Testing: New and Novel Approaches for Predicting Environmental Hazards and Risk Assessment

**470 Developing Weight of Evidence Arguments for Assessing the Acute Toxicity of Chemicals to Fish**

*S.E. Belanger, The Procter & Gamble Company / Global Product Stewardship; J.M. Rawlings, K.A. Connors, The Procter & Gamble Company / Environmental Stewardship and Sustainability Organization; J. Moe, NIVA Norwegian Institute for Water Research; A. Lillicrap, NIVA / Environmental Toxicology; W.G. Landis, Western Washington University / Institute of Environmental Toxicology*

Acute responses of fish to chemicals is generally assessed by an OECD Test Guideline 203 method or equivalent. Animal welfare concerns emerged in the last 2 decades that have resulted in the development of several new methods including fish gill cytotoxicity and fish embryo toxicity tests. In 2013, OECD TG 236 Fish Embryo Toxicity (FET) assay for the estimation of acute fish toxicity was validated and adopted at OECD. A recent regulatory opinion rendered by the European Chemicals Agency challenged ecotoxicologists to develop a holistic weight of evidence (WoE) approach that includes FET and other considerations to address requirements for understanding acute fish toxicity to registered chemicals. In this talk, we review recent developments including the status of knowledge on FET and prediction towards acute fish toxicity, FET and fish QSARs, Fish Threshold Approach thinking, the role of mode of action

(MoA) assignment, and progress in a comprehensive Bayesian Belief Network devoted to WoE that incorporates FET data. FET data continues to be developed for all types of compounds. This has occurred even after the assertion that FET under-predicts neurotoxic compounds relative to fish. Integration of all lines of evidence, ranging from the several hundred FET and corresponding fish data from a wide range of chemicals and MoAs, can point to high likelihoods of predictivity of the FET for many classes of compounds. QSARs based on FET results are particularly robust for neutral organic, phenolic, analine, amine, and charged surfactant compounds (non-polar and polar MoA) and are quantitatively indistinguishable from acute fish QSARs. Chemical classes and MOA that are under-represented in the FET and fish toxicity databases regarding high quality OECD TG 203 and TG 236 studies provide particular challenges including neurotoxic and other bioactive or specifically-acting compounds. Vexing issues, such as the quality of OECD 203 data used as the reference standard to judge validity of the OECD 236, studies lacking analytical (in one or both of the OECD 203 or 236), test chemical solubility, and mode of action assignment remain as problems which will take concerted efforts to solve. That said, these can be addressed by WoE arguments which will be summarized as a proposed process diagram in this talk.

**471 Advancing predictive QSAR and AOP development: 3-dimensional protein modeling, molecular docking, and structure-based pharmacophore approaches**

*M.G. Barron, USEPA / Gulf Ecology Division; S. Lee, Daegu-Gyeongbuk Medical Innovation Foundation*

Traditional approaches to quantitative structure activity relationship (QSAR) modelling have used either single physical-chemical descriptors such as log-Kow or multiple two-dimensional theoretical molecular descriptors. The increasing availability of protein crystal structures and advances in computational chemistry now allow efficient conformer generation and docking in three-dimensional (3D) protein models. 3D QSAR models were developed for aromatase, acetylcholinesterase, and the estrogen receptor. For each model, 3D-fingerprint descriptors encoding protein-ligand interactions were developed using molecular docking and structure-based pharmacophores to rationalize the structural requirements responsible for the activity of a diversity of agonist and antagonist ligands. In silico mutagenesis was also used to understand differences in species sensitivity due to amino acid substitutions at key molecular interaction points. The results show that 3D QSAR models can serve as a predictive framework for quantitative and mechanistic understanding of complex molecular initiating events, and define the chemical applicability domain of specific Adverse Outcome Pathways.

**472 Leveraging Zebrafish to Identify Chemicals Disrupting Early Embryonic Development**

*S. Vliet, S. Dasgupta, D.C. Volz, University of California, Riverside / Environmental Sciences*

Alternatives to conventional toxicity testing are needed to support chemical screening and prioritization. Zebrafish embryos offer one of the most promising cost-effective vertebrate models to support toxicity testing. Therefore, the overall objective of this project was to leverage early, non-protected life stages of zebrafish embryos to identify compounds that disrupt the normal trajectory of early embryonic development. For the first aim, we carried out a high-content screen of the LOPAC[1280] (Library of Pharmacologically Active Compounds) library – a commercially available library of 1,280 marketed drugs, failed development candidates, and well-characterized small molecules widely used for validation of high-throughput screening assays. Based on this screen, niclosamide – an antihelminthic drug used worldwide for the treatment of tapeworm infections – was one of the most potent developmental toxicants within zebrafish embryos during the first 25 h of development, with exposure to 10 µM niclosamide from 5-25 h post-fertilization (hpf) resulting in 100% embryo mortality. Therefore, the second aim of this study was to investigate the mechanism of toxicity of niclosamide during early stages of embryonic development. We found that niclosamide induced a concentration-dependent delay in epiboly progression during late-blastula and early-gastrula, an effect that was dependent on exposure during the maternal-to-zygotic transition – a period characterized by zygotic genome activation and initiation of cell motility. Moreover, we found that niclosamide did not affect embryonic oxygen consumption, suggesting that oxidative phosphorylation – a well-established target for niclosamide within intestinal parasites – may not play a role in niclosamide-induced epiboly delay. However, mRNA-sequencing revealed that niclosamide exposure during late-blastula and early-gastrula significantly impacted the abundance of cytoskeleton- and cell cycle regulation-specific transcripts. Indeed, we found that niclosamide inhibited tubulin polymerization in vitro, suggesting that niclosamide-induced delays in epiboly progression may be driven by disruption of microtubule formation and cell motility within the developing embryo. Overall, our findings highlight the utility of embryonic zebrafish as a physiologically-intact, non-mammalian model for screening and prioritization of chemicals and environmental samples for further testing within rodents and human cell-based systems.

**473 Characterization of the gill cell line RTgill-W1 as an in vitro alternative to in vivo acute WET testing methods**

*J. Scott, ATC Group Services / Integrative Biology; M. Minghetti, J.B. Belden, Oklahoma State University / Integrative Biology*

Current acute Whole Effluent Toxicity (WET) test methods are quite laborious, not very cost effective, and lack detail in identifying a toxicant's mode of action. Fish cell lines offer an inexpensive, high throughput approach, and simultaneous measurement of cellular toxicological endpoints such as metabolic activity, membrane and lysosomal integrity. Due to major roles the gill serves in fish physiology, the cell line RTgill-W1, was evaluated as an in vitro alternative model for acute vertebrate WET testing. Exposure conditions require considerations as RTgill-W1 cells cannot be exposed directly to water samples and require modification of osmolarity through addition of salts to the exposure medium which can affect bioavailability of toxicants. The first step of this study was to compare the 50% effective concentration (EC50) of 14 selected toxicants (commonly found in effluent samples) in isosmotic conditions and correlate them to the 50% lethality concentration (LC50) in freshwater (fathead minnow, *Pimephales promelas*) and marine (sheepshead minnow, *Cyprinodon variegatus*) species from literature. Measured chemical concentrations were confirmed analytically for all exposure conditions. Secondly, we determined cell tolerance to medium of varying osmolality (50 to 1000 mOsm/Kg). In isosmotic exposures 13 of the 14 toxicants tested, showed a significant correlation between in vitro cytotoxicity EC50s and in vivo literature LC50s of both fish species. Cells tolerated osmolality from 150 to 450 mOsm/Kg. Thereafter, cytotoxicity of a subset of chemicals was tested in hyposmotic, and hyperosmotic conditions. Cytotoxicity of Cu was increased by hyperosmotic conditions, and by both hypo- and hyper- osmotic conditions for Ni. Although, these adjustments mimic environmental conditions more closely, they do not represent the actual osmolality of effluent water. Therefore, we are currently investigating whether RTgill-W1 cells cultured on permeable membranes or transwells can tolerate a broader range of media osmolality (5 -1000 mOsm/Kg). Concluding, the ability to correlate in vitro EC50s to in vivo LC50s of several chemicals is a crucial first step in establishing RTgill-W1as an alternative acute WET testing model. Moreover, by determining if RTgill-W1 cells can tolerate direct exposures of various osmotic condition will strengthen this in vitro model's applicability in routine acute WET testing.

**474 Metabolite Profiling of Zebrafish Liver Cell Culture for Environmental Monitoring and Surveillance**

*Q. Teng, J.D. Mosley, H. Zhen, Y. Yue, USEPA / National Exposure Research Laboratory; J.E. Cavallin, Badger Technical Services / National Health and Environmental Effects Research Laboratory; D.L. Villeneuve, G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; D. Ekman, T. Collette, USEPA / National Exposure Research Laboratory*

Anthropogenic chemicals released from waste water treatment plants, as well as industrial and agricultural operations often negatively affect surface water quality. It has been shown in previous studies that exposure to such complex chemical mixtures can cause adverse health effects in ecological organisms. Traditional methods using live animals (e.g., fish) for monitoring and assessing contaminant exposure and impacts in affected ecosystems are both resource and time intensive and thus often impractical for screening large numbers of impacted sites. Cell-based metabolomics is proving useful for conducting rapid assessments of environmental exposures, providing a means to reduce animal use and the associated resource investment. In addition, cell-based metabolomics tools are typically unbiased (or untargeted) thus providing an evaluation of biological effects that may not be monitored for when using other techniques. Finally, a large variety of cell types (both human and otherwise) may be employed to investigate impacts across species and/or in specific tissue types. However, the ability to extrapolate metabolite changes determined in vitro to those that would be anticipated to occur in vivo is an ongoing challenge. In this study, we applied recently developed in-house high-resolution liquid-chromatography mass spectrometry (HR LC-MS) methodologies for detecting hydrophilic and lipophilic metabolites in both zebrafish liver cell cultures (ZFL) and zebrafish liver tissues to assess similarities and differences in the detectable metabolomes. Here we report the results of these analyses, with specific emphasis on those biochemical pathways and networks that are shared (and of greatest potential for making in vitro to in vivo extrapolations) and those are specific to each system. Such an evaluation is a critical step in the development of cell-based metabolomics for environmental monitoring of impacted surface waters.

**475 Use of cell-based models to investigate xenobiotic metabolism of pollution-adapted Gulf killifish (*Fundulus grandis*) from the Houston Ship Channel, TX**

*M.E. Franco, C.W. Matson, R. Lavado, Baylor University / Environmental Science*

High concentrations of dioxin-like compounds have been measured in the Houston Ship Channel (HSC), Texas, USA. However, the Gulf killifish (*Fundulus grandis*), a ubiquitous species inhabiting the HSC, has been recently characterized to be pollution-adapted. Previous studies in the sister species *Fundulus heteroclitus* have suggested that such adaptation is the result of reduced metabolism, mediated by the reduced activity of the aryl hydrocarbon receptor (AhR) pathway and the subsequent downregulation of CYP450 enzymes. To further characterize pollution-adapted populations and to obtain insight into the biochemical mechanisms driving this adaptation, a comparison of ethoxyresorufin-O-deethylase (EROD) activity, as a proxy for CYP1A expression, was conducted between liver microsomes and two established fish liver cell lines. This was based under the hypothesis that low microsomal but high cell-based EROD activity would be observed for pollution-adapted populations. Adult fish were collected from heavily polluted and reference sites, and in situ removal of the liver was done immediately after collection. In the laboratory, microsomal EROD activity was measured and compared between adapted and reference populations. In spite of large differences in exposure to AhR agonists, microsomal EROD activity was not significantly different among these populations, suggesting that the expression of metabolizing enzymes might be reduced in adapted populations. Furthermore, pressurized liquid extractions were obtained from fish tissue from both adapted and reference populations, with the aim of obtaining accumulated AhR agonists, and the fish liver cell lines PLHC-1 and Hepa-E1 were exposed to these extracts for 48 h. EROD activity in Hepa-E1 cells was significantly higher after exposure to fish extracts from polluted sites than to extracts from reference fish, but no differences in EROD activity were observed for PLHC-1 cells. The present study highlights to major observations: 1. pathways regulating xenobiotic metabolism in pollution-adapted populations may indeed be reduced as a mechanism of adaptation to high levels of industrial pollution, and 2. the selection of appropriate cell-based models is imperative when used as tools in toxicological studies and for specific research purposes. The use of in vitro models proves to be advantageous in describing adapted populations of fish and, potentially, other species inhabiting highly polluted environments.

**476 Strategically Selecting Test Species using the Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS) Tool**

*J.A. Doering, USEPA / Mid-Continent Ecology Division; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; B.R. Blackwell, USEPA / ORD / National Health and Environmental Effects Research Laboratory; K. Dean, Oak Ridge Institute for Science Education at USEPA; C. LaLone, USEPA / Mid-Continent Ecology Division; S. Poole, USEPA / Mid-Continent Ecology Div / National Health and Environmental Effects Research Laboratory; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory*

Chemicals in the environment can affect the health of wildlife with the potential for vastly different sensitivities among species. However, toxicity data used in risk assessment is based on a small number of model test species which might not represent the diversity of species sensitivities. This uncertainty is particularly true for many contaminants of emerging concern (CECs), including agonists of the peroxisome proliferator-activated receptor y (PPARy), for which species-sensitivity information might only be available for one or a few species. However, performing toxicity testing for many species to determine the range in sensitivity is not practical. Therefore, the goal of this study was to demonstrate a means of selecting test species in a strategic fashion to demonstrate a computational means of selecting species for toxicity testing for characterizing differences in sensitivity. Specifically, this study used the Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS) tool to rapidly and computationally predict species-specific chemical susceptibility across phylogenetically diverse species through evaluation of structural similarities and differences in the protein target of a chemical. The public literature was used to identify 17 key amino acid residues in the ligand binding domain of PPARy that interact with chemicals, along with knowledge of amino acid differences that cause differences in binding affinity. Differences in these amino acids were investigated among sequences of 246 phylogenetically diverse species using SeqAPASS. Four amino acid positions had differences across species that were predicted by SeqAPASS to potentially result in differences in binding of chemicals and therefore might be important in differences in sensitivity among species. Five PPARy-types were proposed that likely differ in their sensitivity to agonists, namely Type 1 (mammals), Type 2 (birds, reptiles, amphibians, ancient fish), Type 3 (most fish), Type 4 (salmonids), and Type 5 (zebrafish). Based on these results, Xenopus (Type 2), fathead minnow (Type 3), rainbow trout (Type 4), and zebrafish (Type 5) were strategically selected as being representative of the diversity of species sensitivities to agonists of PPARy for ongoing investigation. This study demonstrates how SeqAPASS can be used to computationally predict species most likely to differ in susceptibility to chemicals for the strategic characterization of species differences in sensitivity.

**477 Identification of innate immunotoxicity of perfluorooctanoic acid (PFOA) in zebrafish embryos using in situ hybridization**

*A.M. Pecquet (Willis), J. Yadav, A. Maier, University of Cincinnati / Environmental Health; S. Sumanas, CCHMC Research / Cincinnati Childrens Hospital Medical Center*

Perfluorooctanoic acid (PFOA) is ubiquitous and persistent in the environment and can be found in nearly all environments across the globe. PFOA is detectable in most human serum and environmental media, and is expected to persist given the relatively long half-life. PFOA has been classified as persistent and bioaccumulative, and was recently labeled "*presumed to be an immune hazard to humans*" by the NTP. However, the exact immunotoxicity mechanisms for PFOA have yet to be fully elucidated, and little data exist on the potential for PFOA to modulate innate immune responses or to alter ecological immune responses. Therefore, we investigated the overt innate immune effects of PFOA exposure in zebrafish embryos (ZFEs). ZFEs were exposed to PFOA for 48 hours and the neutrophil chemotaxis assay was applied to stimulate neutrophil chemotaxis and migration to the site of inflammation. Neutrophils were stained using in situ hybridization for the myeloid peroxidase (MPX) protein, and total number of neutrophils were counted in the wounded region across treatments. We were able to show a significant reduction in neutrophil chemotaxis to the wound site in PFOA treated embryos as compared to control for both the low and high dose exposure. Potential mechanisms for this effect could include an overall systemic neutropenia from altered granulopoiesis or alterations to chemotaxis/chemokine signaling, and are currently being explored. Because there is very little information investigating immune effects during early development, windows of susceptibility, or on the ecological impacts of immune modulation, these data are useful in identifying an adverse immune phenotype in a standard ecological model with high relevance to human health. Use of a single model that can be used to identify both ecological and human health effects contributes to the 3Rs aimed at reducing animal testing. Future studies (in progress) will evaluate the mechanistic and genetic pathway modulation in the adverse outcome pathway related to the identified innate immune effects.

## Selenium Ecotoxicology and Management Going on 40: What Do We Know and How Can We Apply It?

**478 Sensitivity of Sturgeon to Copper, Cadmium, Selenium and Zinc**

*W.J. Adams, Red Cap Consulting; D.K. DeForest, A.C. Ryan, R.C. Santore, Windward Environmental, LLC*

The sensitivity of freshwater sturgeon to copper (Cu), cadmium (Cd), selenium (Se) and zinc (Zn) relative to other fish species has drawn the attention of conservation and environmental groups dedicated to restoring sturgeon populations (Acipenseridae) in the U.S. Sturgeon populations have dramatically declined in the 20$^{th}$ century. There is a general consensus that this decline is primarily due to the loss of spawning habitat (siltation) and placement of dams on rivers preventing the return of sturgeon to spawning grounds. However, there is concern that selenium may be limiting reproductive success for green and white sturgeon in San Francisco Bay and that Cu, Cd, and Zn may play a similar role for white sturgeon in the Columbia River and in rivers on the Great Lakes (lake sturgeon). This presentation reviews the available acute and chronic toxicity (aqueous exposure) of Cu, Cd, and Zn to sturgeon species in comparison to other sensitive fish (and invertebrate) species and US Environmental Protection Agency (USEPA) water quality criteria (WQC). The toxicity of dietary selenium to sturgeon and proposed thresholds (egg/ovary, whole body, muscle) relative to those selected by USEPA for species other than sturgeon is reviewed. Briefly, the data show that juvenile sturgeon (30-60 days post-hatch) are one of the more sensitive fish to Cu, Cd, and Zn, but not always the most sensitive. WQC adjusted for bioavailability appear to be protective for sturgeon for these metals. Regarding selenium, green sturgeon have been shown to be more sensitive to dietary selenium fed as selenomethionine than white sturgeon. Fish collected from San Francisco Bay have been reported to contain ovary concentrations that exceed the EPA WQC ovary threshold of 15.1 ug/g dry wt. for sensitive fish. The extent of selenium toxicity data available for assessment will be reviewed.

**479 Reproductive effects of selenium in the fathead minnow (*Pimephales promelas*)**

*T. Lane, University of Saskatchewan; D. Green, K. Raes, University of Saskatchewan / Toxicology Centre; K. Bluhm, University of Saskatchewan / School of Environment and Sustainability; D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences; K. Liber, L.E. Doig, University of Saskatchewan / Toxicology Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre*

Certain aquatic systems are prone to increased loading of the essential trace element selenium (Se) because of natural sources or anthropogenic activities. All animal classes are susceptible to the toxic effects of Se due to the narrow range between essentiality and toxicity; however, egg-laying vertebrates are at especial risk because of maternal transfer of Se. The objective of this study was to characterize the maternal transfer of dietary selenomethionine (SeMet), the primary form of Se in contaminated aquatic food webs, and its effects on the F1 generation in a short-lived fish species native to North American freshwater systems, the fathead minnow (*Pimephales promelas*). Twenty breeding groups (3 females:2 males) were exposed to dietary SeMet at Se-normal levels (1.18 mg Se/kg food, dry mass [dm]) and environmentally relevant levels (3.88, 8.75 or 29.58 mg Se/kg food dm) and bred for 28 days. Embryos were collected daily and total Se concentrations were measured via ICP-MS to establish the kinetics of maternally transferred Se. Embryos collected on days 26, 27 and 28 were reared to swim-up and assessed for hatchability, survival and morphological abnormalities (frequency, type and severity). Upon onset of exposure an immediate deposition of Se into embryos was observed. After 28-days of exposure, embryo Se concentrations were elevated in a dose-dependent manner resulting in a significant difference in mean embryo Se concentrations from the control (1.80 mg Se/kg embryo dm) in the medium (11.74 mg Se/kg embryo dm) and high (27.17 mg Se/kg embryo dm) treatment groups. Exposure to dietary SeMet did not affect fecundity rates among treatment groups. There was no effect of Se exposure on hatchability or survival among treatment groups. Preliminary deformity assessment revealed an increasing, although not significant, trend in the frequency of deformities between the control and high treatment groups ($p=0.062$). To investigate an alternative exposure route as a proxy for maternal transfer, embryo microinjection of fathead minnow embryos was utilized to deliver Se dosages of concentrations analogous to the dietary maternal transfer study. A suite of biological endpoints from the microinjection study and dietary maternal transfer study will be compared to determine if embryo injection is a valid proxy for maternal transfer. If valid, the injection exposure route could be used to support Se research in early life stages of non-model species.

**480 Moving Forward: Implementation of Tissue-Based Selenium Criteria in Absence of Guidance**

*S. Skigen-Caird, S. Pargee, S.P. Canton, GEI Consultants, Inc. / Ecological Division*

EPA's tissue-based selenium criteria were finalized in 2016. Soon thereafter, EPA produced draft implementation guidance documents to assist states and dischargers with interpreting the tissue-based criteria and application of the criteria into states' water quality standards and NPDES permits. However, to-date, these documents have still not been finalized, leaving states with no clear guidance from EPA on how to proceed with adoption and implementation of the tissue-based criteria. This lack of guidance has led to states being hesitant to move forward with the adoption of criteria, given existing uncertainty. GEI has been providing technical support for clients in multiple states for the development of statewide or site-specific tissue-based selenium standards, work is currently ongoing in California, Colorado, Minnesota, Mississippi, Iowa, and Indiana. Many questions have been raised regarding implementation of tissue-based criteria during discussions with the various state agencies and regional EPA offices. In this presentation we will review some of the issues and challenges that have arisen in these discussions, such as fishless streams, underlying geology, resident species, and a disconnect between water and tissue concentrations. We will also discuss some lessons learned, and will present practical considerations for parties interested in developing site-specific criteria.

**481 Laboratory-derived selenium toxicity thresholds for fish and evidence of population-level impacts**

*G. Gilron, Borealis Environmental Consulting Inc.; D. DeForest, Windward Environmental LLC*

There have been some significant recent developments in regulatory guidelines for selenium in North America, specifically: the finalization of the USEPA criteria for selenium (water and fish tissue), the revision of British Columbia aquatic life guidelines (various media), and selenium limits in the proposed federal coal mining effluent regulation in Canada. Based on field collection of fish gametes, and rearing of fertilized eggs in the laboratory, selenium-related reproductive effects have been documented in both the US and Canada. The toxicity data from field-based exposures, together with toxicity data from laboratory-based exposures, were used to develop the criteria and guideline values noted above. While there have been historical accounts of fish population extirpations in the United States over 30 years ago (e.g., Hyco Lake, Belews Lake), those examples were characterized by high-selenium inputs and selenium concentrations in fish tissue that were much higher than current criteria and guideline values. Similar evidence of population-level impacts on fish populations due to elevated selenium concentrations in the receiving environment have not been demonstrated recently in the US or in Canada. We conducted a meta-analysis of fish selenium concentrations in the field that exceed current fish tissue-based selenium criteria and guidelines, and evaluated whether there were corresponding evaluations of population-level effects due to selenium. Based on this review, fish population assessments are not routinely conducted in receiving waters where fish tissue-based selenium criteria or guidelines are exceeded, but, where they have been, the available data indicate that conclusive population-level impacts have not been observed. This indicates that recent fish tissue-based selenium criteria and guidelines are conservative and protective of fish populations. It should be noted that the more recent cases of tissue-based selenium criteria and guideline exceedances, however, are much more moderate than was observed at Hyco and Belews lakes, for example, which may make potential population-level effects more difficult to detect. The available data and associated uncertainties will be discussed.

**482 Nonlethal selenium monitoring in San Francisco Bay white sturgeon: Factors influencing tissue concentrations and implications for long-term monitoring**

*J. Sun, J.A. Davis, San Francisco Estuary Institute; A.R. Stewart, USGS / National Research Program Western Branch; V. Palace, IISD-Experimental Lakes Area*

Selenium is an essential trace element that is toxic at high levels and has been shown to adversely impact reproduction in white sturgeon. To protect this sensitive species, in 2016 the San Francisco Bay Regional Water Quality Control Board established the North San Francisco Bay Selenium TMDL. The TMDL established a target of 11.3 ug/g dw in white sturgeon muscle tissue. In 2015-2017, the Regional Monitoring Program for Water Quality in San Francisco Bay (RMP) conducted two studies to develop non-lethal monitoring methods to assist with TMDL implementation. The first study evaluated relationships between selenium in non-lethally collected muscle plugs and other tissues, including muscle fillet (more commonly used for regulatory monitoring) and ovary and liver tissues (more toxicologically relevant). Tissues were collected from angler-caught adult white sturgeon during a fishing derby held in January-February in North Bay. Results established that muscle plugs are good proxies for muscle fillets in selenium bioaccumulation monitoring, and suggest that plug selenium can also be used as a general indicator of ovary or liver selenium concentration. The second study piloted methods for muscle plug sampling in live sturgeon and selenium analysis in small plug samples. Muscle plugs were collected from 30-60 live white sturgeon annually during fall California Department of Fish and Wildlife sturgeon surveys in the North Bay. Muscle plug selenium concentrations were significantly lower in fall 2017 compared to 2015-2016, immediately following an extended drought period from late 2011 to spring 2017. This finding is consistent with observed patterns in *Potamocorbula amurensis*, a major sturgeon prey item, which have lower selenium concentrations during periods of high freshwater inflow. Significantly lower selenium concentrations were also observed in juvenile compared to adult sturgeon, although no significant pattern was observed among adults across fish lengths. Selenium data were also analyzed in the context of data from previous studies of Bay white sturgeon, to evaluate the effect of additional factors potentially influencing sturgeon selenium concentrations. Freshwater inflow, reproductive maturity, and foraging location were identified as factors driving the high level of variability observed in sturgeon selenium concentrations. This information was used to design a long-term muscle plug monitoring program to assess trends and attainment of the TMDL target.

**483 Characterization of selenium trophic transfer in a boreal lake food web using a whole ecosystem approach**

*S. Graves, K. Liber, University of Saskatchewan / Toxicology Centre; V. Palace, IISD-Experimental Lakes Area; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; L.E. Doig, University of Saskatchewan / Toxicology Centre; D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences*

Human activities such as coal and metal mining have increased the release of selenium (Se) to aquatic environments, but information about the trophic transfer dynamics of Se in Canadian boreal lake systems is lacking. The goal of the present study was to characterize the uptake and trophic transfer of Se after addition to in situ enclosures located in Lake 114 at the International Institute for Sustainable Development – Experimental Lakes Area (IISD-ELA) in northwestern Ontario. In June 2017, Se was added to 3000 L littoral enclosures as sodium selenite to reach nominal concentrations of 1 µg/L (actual concentration (mean ± SD) = 1.01 ± 0.15 µg/L) and 10 µg/L (actual concentration = 9.58 ± 2.63 µg/L) in triplicates for 77 d, and three additional enclosures were controls with no Se added (background concentration = 0.28 ± 0.04 µg/L after 77 d). Ecosystem level characterization of exposure and trophic transfer were determined by measuring total Se (TSe) concentrations in water, sediment, periphyton, benthic macroinvertebrates, and female fathead minnows (*Pimephales promelas*; added on d 33) collected at the end of the exposure period. Mean (± SD) periphyton Se concentrations after 77 d were 2.95 ± 0.71, 11.92 ± 2.52, and 71.36 ± 18.06 µg/g dw in control, 1 µg/L and 10 µg/L treatments, resulting in enrichment functions (EFs) of 11891 ± 1754, 12142 ± 3208, and 7431 ± 2292, respectively. Se in surface sediments was higher in the 10 ug/L treatment (21.90 ± 4.74 µg/g dw) than in the control and 1 µg/L treatment (2.58 ± 0.58 and 3.68 ± 1.74 µg/g dw, respectively). Trophic transfer factors (TTFs) for benthic invertebrate taxa ranged from 0.6 for Gammaridae to 3.5 for Chironomidae over all treatments. Fathead minnow ovary Se concentrations were 6.91 ± 0.45, 10.87 ± 1.04, and 45.51 ± 2.20 µg/g dw in control, 1 µg/L and 10 µg/L treatments, respectively. Se was enriched by up to four orders of magnitude by periphyton, and Se in fish ovaries accumulated to concentrations near or above the current USEPA criterion (15.1 µg/g dw for fish ovary/egg) at 1 and 10 µg/L exposure levels, suggesting that Se has the potential to accumulate to levels of concern at these concentrations and could pose a toxicity risk to sensitive organisms (i.e. fish and birds) in colder water ecosystems like Canadian boreal lakes. In addition, differences in Se concentrations among potential prey items of fish may influence Se accumulation in lake food webs and warrant further study.

**484 Trophic Considerations: Assessing the Trophic Transfer of Selenium to an Amphipod (*H. azteca*) Through A Diet of Field-Collected Biofilm Communities**

*K. Raes, L.E. Doig, K. Liber, University of Saskatchewan / Toxicology Centre; D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences; B. Markwart, University of Saskatchewan / Toxicology Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre*

Understanding the mobilization and accumulation of selenium in the environment is a growing global priority. Toxicological concerns exist particularly due to the detection of devastated oviparous vertebrate populations, triggered primarily by the teratogenic effects of selenium exposure. Natural and anthropogenic sources, and site-specific differences in biogeochemistry result in different concentrations, species, and bioavailabilities of selenium in aquatic environments. Inorganic forms of selenium (eg. selenate [SeO4?²] and selenite [SeO3?²]) are biotransformed and bioaccumulated by microorganisms into organoselenium compounds, which are transferred to higher trophic levels principally via dietary pathways. The present study quantified the trophic transfer factors of selenium to a primary consumer through the bioconcentration and biotransformation of inorganic oxyanion species by field-collected biofilms. Samples were exposed in the laboratory to aqueous concentrations of selenite and selenate respectively, at concentrations of 0, 5 and 25 µg Se/L, and uptake by the biofilm was quantified. The amphipod *Hyalella azteca*, a primary consumer characteristic of Canadian freshwater ecosystems, grazed on the selenium-spiked biofilm communities to determine trophic transfer efficiencies as a function of community structure. Selenite was transferred in a dose-dependent fashion and final tissue selenium concentrations varied by site. *H. azteca* tissue selenium reached up to 6.47 ± 0.24 ug Se/g in the low treatment and 20.72 ± 6.06 ug Se/g in the high treatment. Trophic transfer factors from the biofilm to the invertebrate ranged from 0.16 – 0.44 in the low treatment and 0.13 – 0.34 in the high treatment. Selenate trophic transfer did not differ from control across all sites. This research will serve to assist in improving environmental risk assessment strategies for the release of selenium into aquatic environments.

**485 Effects of selenium speciation on bioaccumulation downstream of a biological water treatment plant**

*A.M. deBruyn, Golder Associates Ltd; S.N. Luoma, University of California, Davis / John Muir Institute of the Environment; P.L. Orr, Minnow Environmental Inc.; J. Elphick, Nautilus Environmental; K. Brix, EcoTox / Marine Biology and Ecology; M. Hafke, M. Digel, Teck Coal Limited*

Biological treatment of selenium acts via microbial transformation of aqueous selenate (VI) to reduced species such as selenite (IV) and organoselenides (II). This process lowers aqueous total selenium concentrations, but can alter the bioavailability of the remaining selenium. We found increases in selenium bioaccumulation downstream of an active water treatment plant, despite reductions in total aqueous selenium concentrations. We combined laboratory algal uptake tests, field measurements of bioaccumulation, and selenium speciation analysis of treated effluent and receiving waters to develop a model of selenium bioaccumulation that explictly accounts for speciation. We quantitatively attributed the observed increase in bioaccumulation to reduced species, including selenite, dimethylselenoxide, and methylseleninic acid. We then applied this model to predict how bioaccumulation would be affected by a post-treatment oxidation step that returns effluent speciation to a selenate-dominated condition.

## In Situ Treatment of Contaminated Sediments – What Are the Remaining Barriers?

**486 Placement and Measurement Challenges: Methodology for Evaluating Installation and Testing of As-Placed Activated Carbon Amendments**

*J. Collins, AquaBlok, Ltd.; G.M. Braun, Tetra Tech, Inc.; K. Craigie, Tetra Tech Inc; S. Collins, AquaBlok, Ltd.*

Background. The successful use of activated carbon or other reactive materials for in-situ sediment treatment (via contaminant sequestration and immobilization) or the incorporation of these materials into reactive caps has been studied and demonstrated at numerous sites worldwide over many years. To determine the form and quantity of activated carbon required and the design of an in-situ treatment remedy, treatability studies have often been performed along with modeling, and assumptions are made from these studies that are important to the ultimate success of the remedy. It is important to be able to verify that the intended design was properly constructed. However, key aspects related to full-scale installation and quality control may be limiting expansion and more broad-based acceptance of this sediment remediation approach. Challenges have been experienced in quality control related to both evaluation of placement/installation and verification of as-placed activated carbon and organoclay content at the sediment surface. This presentation will focus on the means and methods successfully utilized to address these challenges. Approach/Objectives. Three aspects of the use/application of activated carbon for sediment remediation will be discussed. First, an overview of the impact of activated carbon material selection will be provided. Second, a discussion of treatability studies and data evaluations used to develop the design assumptions and the importance of confirmation of modeling and design aspects. Finally, an overview of a large-scale project will be presented to illustrate methods that have been successfully utilized to provide post-placement confirmation of installation. Aim. Field results demonstrate that the appropriate material selection and application of powdered activated carbon can provide significant reductions in pore water contaminant concentrations of PCBs and corresponding reductions in bioavailability as documented by contaminant up-take in target species. The goal is to reduce uncertainty and risk associated with remedy implementation. This presentation will provide important information related to both activated carbon selection and methods used to verify the successful placement of the material to support an In-Situ treatment approach to contaminated sediment remediation.

**487 In situ evaluation of using clean dredged material as an alternative to clean sand for enhanced monitored natural recovery**

Markillie, Naval Facilities Engineering Command Pacific*

Portions of Pearl Harbor have been selected for remedial action under a Record of Decision due to elevated sediment concentrations for contaminants including cadmium, copper, lead, mercury, zinc, and total polychlorinated biphenyls (tPCBs). While Enhanced Monitored Natural Recovery (EMNR) has been successfully demonstrated with clean sand, the use of uncontaminated natural sediment as a cap substrate, currently termed true EMNR (tEMNR), should allow uncontaminated sediment with a natural level of binding capacity (primarily associated with organic carbon and fines content) to sequester contaminants and enhance recovery when compared with traditional EMNR. This study explored the potential value of using locally available clean dredged material in a thin layer cap, in direct comparison with other common sediment remedies, at a mesocosm scale using a series of field-deployed Remedy and Recontamination Assessment (RARA) arrays. RARA arrays were designed to provide a site-specific, direct measurement of recontamination potential and impact on a range of remedies while providing increased realism compared to laboratory treatability studies and reduced costs and complexity compared to large-scale field pilot studies. The arrays, housing multiple 18-gallon polyethylene treatment cells, were placed in an area of Pearl Harbor currently being considered for EMNR, and contain Pearl Harbor site sediment treated with a thin-layer of each of five treatments: 1) low carbon dredged material; 2) high carbon dredged material; 3) clean sand; 4) powdered activated carbon (AquaGate +PAC™); or 5) control (no treatment). The arrays incorporate standard cylindrical sediment traps to capture incoming depositional sediments, and also house an ADCP and data sondes to characterize hydrodynamic and water quality conditions, respectively, during the deployment. In addition to two monitoring events involving deployment and recovery of porewater passive sampling devices (i.e. polyethylene for PCBs and diffusive gradients in thin film (DGT) and peepers for metals) during the study, recovery of the arrays will allow for a range of endpoints including final sediment chemistry, bioaccumulation, and benthic community composition to provide the basis for evaluating effectiveness of the various remedies and potential recontamination from deposited material following a ~12-month field deployment.

**488 In Situ Passive Sampling for the Evaluation of Carbon Amendment Performance**

*A.V. Smith, Texas Tech University / Civil, Environmental, and Construction Engineering; T. Hussain, Texas Tech University / Department of Civil Environmental and Construction Engineering; S. Yan, Texas Tech University / Chemical Engeneering; M. Rakowska, National Research Council of the National Academies/ USEPA – AED / Civil and Environmental Engineering; D.D. Reible, Texas Tech University / Civil and Environmental Engineering; C. Owens, A. Reese, Apex Companies, LLC; J. Sutter, H. Nelson, Oregon DEQ*

In 2006, the Portland District of the U.S. Army Corps of Engineers collected sediment samples from varying depths near a portion of the Lower Columbia Slough at the Pacific Meats cleanup site. Sediment samples presented polychlorinated biphenyl (PCB) concentrations up to 2,450 µg/kg. The PCB concentrations were found to be higher in the Lower Slough than in other reaches and were detected more consistently within the more industrial and commercial development of this area. In 2015, Texas Tech University performed a baseline study by evaluating in situ and ex situ porewater sample analyses at 20 locations at two depth intervals (0-13.5 cm and 13.5-29 cm). In situ sampling was performed by solid-phase microextraction (SPME) passive sampling using polydimethylsiloxane (PDMS) coating on a glass fiber to act as a sorbent for PCBs. In 2017, a thin cap of activated carbon (AC) was placed across two separate plots (East and West). After the placement of AC in two forms, the analysis and comparison of pore water concentrations within the 20 approximately identical cap locations across the two plots was determined. SPME samplers were deployed in triplicate in the sediment for 28 days to achieve equilibrium with the contaminants of concern for both the baseline analysis and the carbon amendment results. The reductions from the baseline porewater concentrations ranged from 68-98% in the surficial sediment layer, and a central tendency of 90% reduction in porewater concentrations was presented for both the surface and deeper layer across both AC plots. Environmental drivers are presented as an indicator for the sediment porewater exchange rates and reduction of PCBs throughout the site.

**489 Evaluation of porewater reductions due to carbon placement via SedimiteTM and AquaGateTM at a contaminated sediment site**

*M. Rakowska, National Research Council of the National Academies / USEPA – AED / Civil and Environmental Engineering; S. Yan, Texas Tech University / Chemical Engeneering; T. Hussain, Texas Tech University / Department of Civil Environmental and Construction Engineering; X. Shen, Texas Tech University / Civil Environmental Engineering Department; T. Himmer, C.A. Irvine, J. Eby, Jacobs; R. Paulding, US Navy; D.D. Reible, Texas Tech University / Civil and Environmental Engineering*

Contaminant flux and availability in impacted sediments can be significantly reduced with activated carbon (AC) amendment technology. AC is more often placed as a composite material to aid in settling and retention at the sediment surface. A demonstration of two such composite materials, Sedimite and Aquagate, was conducted in open water near Hunters Point Naval Shipyard (HPNS), CA. In this study, changes in freely dissolved concentration ($C_{\mathrm{free}}$) of polychlorinated biphenyls (PCBs) in the surface sediments and in deeper layers (i.e., 30 cm below the sediment surface) were evaluated by in situpassive sampling using polydimethylsiloxane (PDMS) coated fibers.Bioaccumulation reductions in bivalves exposed to AC materials was also assessed and compared to co-deployed passive samplers.*In situ*monitoring of $C_{\mathrm{free}}$with passive samplers was conducted before sediment amendment and up to 26 months following AC placement. Passive samplers with 34.5 µm PDMS coating were preloaded with a wide array of $^{13}C_{12}$PCB congeners as performance reference compounds (PRCs). PDMS samplers were inserted to unshielded holders, attached to a tripod frame and embedded vertically 30 cm into the sediment at20 sampling locations. After 28 days the fibers were retrieved, sectioned into a 1-6, 6-11, 11-16 and 21-26 cm segments below the sediment surface and analyzed for PRCs and 111 PCB congeners. Baseline sampling showed uniform $C_{\mathrm{free}}$across the site with lower concentrations in the near surface versus the deeper layers due to exchange with the overlying water from the shallower zone. Post-placement monitoring showed an 83% decrease of $C_{\mathrm{free}}$after 8 months in the surficial layer with further reductions reaching 90% after 26 months. Smaller but significant reductions in $C_{\mathrm{free}}$was also noted at the deeper depths, which continued to improve with time in line with AC mixing. Bioaccumulation of PCBs in clams (*Macoma Nasuta*) showed very good agreement with predictions from measured $C_{\mathrm{free}}$using equilibrium partition theory. The presentation provides information on the effectiveness of AC by means of $C_{\mathrm{free}}$measurements and discusses the advancement of AC technology based on results from this demonstration as well as earlier AC studies conducted at HPNS site.

**490 Assessment of In-situ Treatment of Multicomponent Contaminated Sediment using Activated Carbon under Differing Levels of Contamination and Disturbance**

*Y. Cho, Stanford University / Civil and Environmental Engineering; J. Pritchard, Stanford Unviersity; M. Whelan, Anchor QEA LLC / Natural Resources; C.R. Patmont, Anchor QEA, LLC; R. Luthy, Stanford University / Civil & Environmental Engineering*

Since the first field trial of in-situ treatment using activated carbon (AC) sorbent was launched at Hunters Point Former Naval Shipyard, CA in 2004, numerous field studies followed and successfully demonstrated its effectiveness in reducing the aqueous and biological availability of various hydrophobic organic contaminants (HOCs) associated with sediments in aquatic ecosystems. Even with the demonstrated effectiveness, there is still a reluctance for regulatory agencies, responsible parties, and other stakeholders to select this technology as a full remedy. Much of this reluctance is because this relatively new and innovative remedial technology has, by definition, not yet yielded long-term monitoring results under varying site-specific conditions. For example, the performance of the AC technology under different levels of localized site disturbances (e.g. potential scour by vessels) and on-going contaminant influx have limited long-term results in the field. To help address this perceived gap, we proposed a pilot study at the former United Heckathorn site at Lauritzen

Channel in Richmond, California, where sediments were impacted by DDT and various co-contaminants. Successful laboratory tests showed the benefit of about 4% AC dose in treating DDT levels ranging from several ppm to 2000 ppm. In the field study, we will assess the application of AC as a blended cover mixed with sand/or gravel. We will assess the blended cover's performance, stability, and other remedial benefits. The blended cover is specifically designed to increase the material layer's resistance to erosion, accommodate localized turbulence, promote helpful mixing of AC with sediment, and limit scour depths. This pilot study will evaluate the feasibility of the in-situ AC technology under various site conditions: localized hydrodynamic disturbance, varying contaminant sediment concentrations, and on-going contaminant influx. This presentation will focus on the pilot study design and preliminary treatability study results.

**491 A novel, activated carbon-based material for the in situ remediation of contaminated sediments**

*S. Abel, J. Carreres Calabuig, J. Akkanen, University of Eastern Finland / Department of Environmental and Biological Sciences*

Using activated carbon (AC) for the in-situ treatment of contaminated sediment has been established as a promising alternative to traditional remediation methods. However, a recent field test in Lake Kernaalanjärvi (Finland) has indicated that this cost-effective remediation method can have significant shortcomings. The major problem encountered was an insufficient stability of the applied AC thin layer cap. The high losses of the capping material were caused by turbulent water conditions due to the large surface area and shallow depth of the lake and the fine particle size of the applied AC (< 100 µm). While these powdered ACs (PAC) have been found to achieve the highest contaminant binding efficiency, their low bulk density facilitates their unintended transport. In addition, they can cause stronger adverse effects to organisms than granular ACs (GAC). However, the latter was found to bind the PCBs from the lake's sediment insufficiently. Therefore the development of a novel remediation material was initiated. To achieve an improved stability in turbulent waters and high remediation efficiency, PAC and clay were fused together under high heat to form stable aggregates. $NaHCO_3$ was added to increase porosity. In the resulting, sandstone-like material, a large share of the PAC's surface remains exposed to the surrounding matrix. The larger overall particle size and added bulk of the aggregates aim at an improved resistance against water movements and lowered adverse effects. Furthermore, the material sinks rapidly through the water column, which eases its amendment and reduces losses due to drift from the intended application site. The aggregates were produced with a grain size of 400 – 1000 µm and compared to GAC of the same particle size. Doses of 0.75, 2, 4 and 7.5 % (based on AC content and sediment dry weight) were applied to natural, PCB-contaminated sediment. *Lumbriculus variegatus* and *Chironomus riparius* larvae were used as test organisms. The novel material showed significantly higher remediation efficiency than the GAC in similar doses, with a reduction in PCB-bioaccumulation of up to 93% (*L. variegatus*) and 82% (*C. riparius*). Significant adverse effects of the novel material were not observed for *C. riparius* and only for 4 and 7.5 % doses for *L. variegatus*. Although at an early point in development, the AC-clay aggregates have shown a promising potential as an alternative in environments with unsuitable conditions for other AC-based materials.

**492 The challenge of measuring activated carbon dose in sediments**

*J. Damond, University of Maryland Baltimore County / Department of Chemical, Biochemical, and Environmental Engineering; C. Gilmour, Smithsonian Environmental Research Center; U. Ghosh, University of Maryland Baltimore County / Chemical, Biochemical, and Environmental Engineering*

The use of activated carbon (AC) for sediment remediation has increased in acceptance and application for in-situ remediation of persistent organic pollutants (POPs) and hydrophobic organic compounds (HOCs). In-situ application has demonstrated that an addition of 1-5% black carbon material can significantly reduce bio-uptake into aquatic food webs. The most important factor in the success of the technology is the dose and uniformity of AC that is actually delivered and persists in sediments post application. However, there is no standard method to measure the amount of AC in sediment, and researchers have used a variety of techniques including measures of total organic carbon, loss on ignition, traditional black carbon determination, and a specialized method for AC. In this work, two different carbon treatments (AC and Biochar) were measured for the amount of black carbon after 7 years of implementation in a field pilot study. Three analytical methods (loss on ignition, total organic carbon, and specialized AC measurement) were compared for the efficacy of measuring the amount of black carbon present in the sediments. A comparison of the accuracy and precision of each method and recommendation for adoption is presented in this study. Accurate measurement of AC in sediments as demonstrated in this study is necessary to build confidence in the adoption of in-situ remediation of sediments.

**493 Assessing the Effects of Activated Carbon-based Amendments on the Bioavailability of Methylmercury from Marsh Sediments to Aquatic Invertebrates**

*S.B. Kane Driscoll, K. Kulacki, Exponent Inc. / EcoSciences; D. Farrar, US Army Corps of Engineers / Engineer Research and Development Center; C. Gilmour, Smithsonian Environmental Research Center; S.S. Brown, The Dow Chemical Company / Environmental Remediation and Restoration*

Studies were conducted to evaluate the effect of activated carbon (AC) amendments on the bioaccumulation of methylmercury (MeHg) in marsh sediments to *Leptocheirus plumulosus*, a representative benthic test organism. In one study, effects of two types of AC amendments—powdered AC and SediMite$^{TM}$ (a pelletized agglomerate of powdered AC)—were compared to an unamended control sediment. In another study, the effects of powdered AC in a newly amended sediment and a powdered AC-amended sediment aged under field conditions for 20 months were compared to an unamended control. Concentrations of MeHg in porewater were also examined as a measure of bioavailability. Samples of surficial marsh sediment were homogenized and sieved to remove plant material. Sediment from each treatment was allocated to replicate test beakers, and redox conditions were re-established before adding test organisms. Samples were collected periodically for analysis of sediment (MeHg and sediment organic carbon), porewater (MeHg), and tissues (MeHg and lipids). Redox conditions and pH were monitored continuously. Several prior tests were performed to develop a method that would preserve MeHg concentrations in test soils during the exposure period. Soil and porewater Hg, MeHg and related geochemistry were tracked carefully prior to and during exposure in both studies. In both experiments, concentrations of MeHg in porewater were significantly lower in all AC treatments compared to the unamended control. Larger reductions in porewater concentrations in comparison to the unamended control were observed in the freshly amended AC treatment (up to 50-fold) than in the aged AC treatment (up to 4-fold). Two to three-fold reductions in tissue concentrations were observed in the freshly amended AC treatments and significant differences between freshly amended AC treatments and unamended controls were observed on Day 7 and 14 in one study, and on Day 21 in the other study. Concentrations of MeHg in tissue from the aged AC treatment were significantly higher than in the unamended control, possibly reflecting significant increases in MeHg in the aged AC treated sediment over the course of the experiment. After normalizing tissue concentrations to sediment concentrations (i.e., accounting for differences in sediment MeHg concentrations) results indicate that both fresh and aged AC decreased bioavailability of MeHg (up to ~3- to 4-fold) in comparison to the unamended sediment.

## Developments in Water Quality Monitoring and Analytical Methods in Support of Water Reuse – Part 2

### 494 Non-target Characterization of Endocrine Active Mixtures Impacting Minnesota Sunfish Spawning Habitats

*M.E. Guyader, Colorado School of Mines; L. Warren, St. Cloud State / Aquatic Toxicology Laboratory; E. Green, Colorado School of Mines; C.M. Butt, Sciex / Nicholas School of the Environment; G. Ivosev, Sciex; R. Kiesling, USGS / Minnesota Water Science Center; H.L. Schoenfuss, St. Cloud State University / Aquatic Toxicology Laboratory; C.P. Higgins, Colorado School of Mines / Department of Civil and Environmental Engineering*

Environmental trace organic contaminant (TOrC) mixtures are suspected to have additive or synergistic adverse effects on wildlife. The objective of this study was to identify components of aqueous TOrC mixtures at Minnesota sunfish spawning habitats that may contribute to the endocrine disruption of resident fish. Porewater samples from four sunfish spawning habitats within the same lake were analyzed using high-resolution mass spectrometry (HRMS). Blood vitellogenin concentrations from captured adult male bluegill sunfish served as biological endpoints of estrogen agonism to bin sites as either Active or Inactive. We hypothesized sites with more pronounced estrogen agonism (Active) would share unique features at higher intensities relative to Inactive sites. Non-target features of interest were prioritized according to multivariate (Principal Component Analysis; PCA and Principal Component Variable Grouping; PCVG) and univariate (two-tailed t-test) analyses. Active and Inactive samples showed unique clustering patterns within PCA scores plots. Corresponding features in visually notable PCVG groupings with significantly (t-value > t-critical) higher intensities in all Active replicates were prioritized for identification. Reported features were identified using existing spectral libraries or in silico fragmentation databases and ranked according to established confidence standards.

### 495 Not My Fish: Using acoustic telemetry to explain contaminant variation in sentinel species along the OCSD outfall

*E. Burns, CSU Long Beach, Shark Lab / Biology; J.L. Armstrong, K.A. Sakamoto, D. Tang, Orange County Sanitation District / Environmental Laboratory & Ocean Monitoring Division; C.G. Lowe, California State University-Long Beach / Biological Sciences*

To abide by permit requirements approved by the EPA and RWQCB, ocean monitoring staff at the Orange County Sanitation District (OCSD) regularly monitor tissue contaminant levels (e.g., PCBs and DDTs) in demersal fishes that are locally abundant. Results have shown high contaminant variation both within and among species across sampling sites located ~8 km apart. Variation in contaminant levels may be explained by differences in inter- and intra-species movement patterns, resulting in some individuals experiencing different levels of contaminant exposure. In this study, acoustic telemetry (Vemco Positioning System) is used to gather data on the movement patterns of tagged individuals that can be used to determine which species are consistently exposed to contaminants from the OCSD outfall and are thus appropriate indicator species of its wastewater effluent. One hundred fifty fish in the orders Pleuronectiformes (flatfishes) and Scorpaeniformes (scorpionfishes and rockfishes) were tagged in regions surrounding the outfall pipe and at a nearby reference site (~8 km upcoast) between March and June 2017. Preliminary results suggest that pleuronectiform fishes are highly mobile and capable of moving up to 8 km in less than 10 hours. These fishes appear to cover large areas that change daily (95% Brownian Bridge KUD: 0.043 ± 0.039 $km^2$ (n=46) at the outfall site; 0.178 ± 0.271 $km^2$ (n=17) at the reference site), and do not appear to show a long-term association to the outfall pipe, as most individuals left the array within two months of tagging. Scorpaeniform fishes, on the other hand, remained within small areas (95% Brownian Bridge KUD: 0.011 ± 0.015 $km^2$ (n=53) at the outfall site; 0.0003 ± 0.0004 $km^2$ (n=3) at the reference site) near the outfall diffuser region for several months. These data indicate that scorpaeniform fishes are more appropriate indicators of wastewater effluent effects than pleuronectiform fishes, as they are more likely to be chronically exposed to contaminants surrounding the outfall. The results further demonstrate that acoustic telemetry is a useful tool for selecting appropriate indicator species for monitoring purposes and assuring that comparisons of tissue contaminant data of sentinel species are scientifically defensible.

### 496 Human Exposure Assessment and Relative Source Contribution of Phthalates and its Metabolites in China's Drinking Water

*M. Ding, S. Zhang, F. Zhao, Q. Kang, J. Hu, Peking University*

Phthalates are endocrine disruptors that are commonly found in drinking water and have received wide attention due to their high yields and reproductive developmental toxicity, simultaneously, phthalates monoesters have been recognized as the bioactive metabolites, which could elicit stronger reproductive toxicity than their parent compounds. As drinking water is a major exposure pathway of contaminant, it is crucial to investigate the concentrations and distributions of phthalates and monoesters in drinking water, estimate human exposure of these compounds, and assess their relative source contributions (RSCs) of drinking water. However, there was little paper to systematically calculate contributions for phthalates and monoesters in drinking water. In this study, phthalates and their metabolites were frequently detected in drinking water from 100 drinking water treatment plants of 24 cities in China. The mean concentrations for DMP, DEP, DiBP, DnBP and DEHP in drinking water were 74.9 ± 516, 22.1 ± 42.6, 232 ± 787, 473 ± 1349 and 148 ± 258 ng/L, respectively. The primary metabolites, MMP, MEP, MiBP, MnBP and MEHP, and secondary metabolites of DEHP, MEHHP, MEOHP, and MECPP were for the first time detected in drinking water with the mean concentration of 12.4 ± 18.5, 2.3 ± 6.0, 11.3 ± 38.3, 37.3 ± 113, 9.4 ± 18.1, 0.25 ± 0.49, 0.15 ± 0.34 and 0.12 ± 0.38 ng/L, respectively. Geometric mean concentrations of urinary MMP, MEP, MiBP, MnBP, MEHP, MEOHP, MEHHP and MECPP were 10.1, 19.3, 29.6, 47.3, 3.6, 6.0, 11.6, 14.4 μg/g creatinine, respectively, in 1040 participants of 16 cities of China, thus the total daily intakes (TDIs) of DMP, DEP, DiBP, DnBP, DEHP for Chinese population were calculated to be 0.32, 0.64, 1.05, 1.41, and 1.33 μg/kg bw/day, respectively. The RSC of DEHP in drinking water was 0.52%, which was lower than 1% suggested by WHO, and of DMP, DEP, DiBP and DnBP, RSCs were 0.05%, 0.03%, 0.36% and 0.26%, respectively. In addition, the contributions of MMP, MEP, MiBP and MnBP in drinking water were 0.14%, 0.02%, 0.05% and 0.10%, respectively. This was the first time to obtain the RSCs of phthalate metabolites in drinking water.

### 497 Surface and groundwater pollution with municipal waste in a water scarce metropolis: A study of Lagos State, Nigeria

*O.O. Olanrewaju, University of Agriculture / Dept of Environmental Management and Toxicology; K.I. Adegbite, Federal University of Agriculture Abeokuta / Department of Environmental Management and Toxicology; F.F. Oyebanji, Federal University of Agriculture Abeokuta / Department of Enviromental Management and Toxicology; I. Oluwadare, Institute of Public Analyst of Nigeria; T.A. Arowolo, Federal University of Agriculture Abeokuta / Department of Environmental Management and Toxicology*

The use of dumpsite instead of landfill systems for municipal waste disposal is a common method in many developing countries which is usually far from recommended standards. Dumpsite are sources of surface and groundwater pollution due to the production of leachate and its migration through refuse. Municipal Solid Waste (MSW) disposal within the Lagos metropolis is of concern as poverty, population growth and high urbanization rates combined with ineffective and under-funded municipalities to prevent the efficient management of wastes. This study assessed the concentration of Poly Brominated di-Phenyl Ether (PBDEs) in leachate and water from four active and one abandoned dumpsites within the Lagos metropolis using standard methods and analysed using GC-MS. The mean concentrations ranged from 7.11±10.1 (Ikorodu) to77.5±109.6 $\mu gL^{-1}$

(Abule Egba) for BDE 28; 5.37±0.3 (Olusosun) to 31.5±27.3μg$L^{-1}$ (Abule Egba) for BDE 47; 17.01±24.1(Abule Egba) to183.1±225.7 μg$L^{-1}$ for BDE 100; 11.7±16.5 (Abule Egba) to173.5±216.5 μg$L^{-1}$(Epe) for BDE 99; 117.4±166 (Abule Egba) to 2033.5±2819.4 μg$L^{-1}$(Epe) for BDE 183; 295.8±391.6 (Ikorodu) to 4282.6±1277.5 μg$L^{-1}$ (Epe) for BDE 209. Olusosun, Solous. Abule Egba had the highest concentrations of BDEs 28 and 47 while Epe dumpsite had the highest concentrations of BDEs 100, 99, 183 and 209. Figure 2 shows the mean concentrations of PBDEs in leachate samples from the five dumpsites in Lagos state. BDEs 28 and 153 were not detected in all the leachate samples from the five sites. BDE 154 was only detected at leachate of Olusosun dumpsite. The mean concentrations ranged from 5.80±1.94 (Epe) to 16.9±9.13 μg$L^{-1}$ (Abule Egba) for BDE 47; 3.9±5.95 (Abule Egba) to 119.3±149.9 μg$L^{-1}$ (Ikorodu) for BDE 100; 1.4±1.98 (Abule Egba) to 105.2±140.4 μg$L^{-1}$ (Ikorodu) for BDE 99; 17.5±24.8 (Abule Egba) to 942±1298.7 μg$L^{-1}$ (Ikorodu) for BDE 183 and 35.7±18.7 (Abule Egba) to 7775±7036.6 μg$L^{-1}$ (Olusosun) for BDE 209. BDE 47 had the highest concentration at Abule Egba dumpsite while its least concentration was recorded at Epe dumpsite. In all the five sites, Olusosun dumpsite leachate had the highest $?_8$PBDES of 8470.35μg$L^{-1}$ It can be concluded from the study that municipal solid waste contributes significantly to PBDEs pollution of surface and groundwater pollution within the Lagos metropolis. Also, there is urgent need to put in place remediation programmes to clean contaminated water to prevent future outbreak of water borne diseases within the metropolis.

**498 Effects of NPs (TiO2) in Wastewater on the Plant Uptake of Contaminants**

*A. Mawof, S. Prasher, McGill University Macdonald Campus / Bioresource Engineering; S. Bayen, S. George, McGill University Macdonald Campus / Food Science and Agricultural Chemistry; C. Nzediegwu, McGill University Macdonald Campus / Bioresource Engineering; E. ElSayed, The University of Guelph / School of Engineering*

Freshwater demand for irrigation is increasing with the food demand of the growing global population. At the same time, industrial development and the expanding urbanization are also demanding more freshwater, resulting in an increasing volume of wastewaters (WW). Many countries are facing the problem of freshwater scarcity and wastewater disposal. As a result, farmers in several developing countries are using, knowingly or unknowingly, partially treated and/or untreated WW to irrigate crops. The presence of contaminants including heavy metals, hormones, pharmaceuticals and personal care products in WW are harmful for environment and human health. In addition, titanium dioxide nanoparticles (NPs-$TiO_2$) have also been detected recently in WW; and their interaction with contaminants in soil-water systems is unknown. $TiO_2$ could interact with WW contaminants and reduce their mobility and uptake by plants. A field lysimeter study has been conducted for two years (2017 and 2018) to investigate the effect of $TiO_2$ on the mobility of heavy metals to potatoes. Potatoes were planted in a sandy soil and irrigated with WW supplied with/out NPs. The WW itself contain organic contaminants and heavy metals (Cd, Zn, Cu, Fe, Pb, and Cr). The edible parts of potato plant (flesh and peels) are used to examine the presence of heavy metals levels using ICP-MS. Results for the first season showed that the presence of NPs in WW reduced lead level in potato peel to 0.2 μg/g as compared to 0.5 μg/g in control (WW without NPs); NPs did not affect the translocation of lead to the flesh of potato (0.24 μg/g in both the treatments). In potato peels, NPs in WW reduced cadmium level to 1.5 μg/g as compared to 11 μg/g in WW without NPs; the corresponding concentrations in potato flesh were 0.45 μg/g and 2.0 μg/g. From the early studies it seems, generally, heavy metals were found to be retained in soil when nanoparticle was added to the wastewater. The results of second year would confirm the findings.

**499 Study on the heavy metal adsorption characteristic of graphene oxide-based calcium alginate bead and its magnetic bead**

*Z. Li, M. Li, Fujian Agriculture and Forestry University / Department of Food Safety / College of Food Science; J. Pang, B. Zheng, Fujian Agriculture and Forestry University / College of Food Science; B.D. Hammock, University of California – Davis / Department of Entomology & UCD Comprehensive Cancer Center*

At present, water pollution caused by heavy metal ions is still a big problem and has become a serious threat to human and aquatic lives. Therefore, special concern must be paid to the treatment of heavy metal ions. In our research, graphene oxide-based calcium alginate beads and its magnetic beads were prepared by using the advantages of graphene oxide and sodium alginate to adsorb heavy metal cations. They were prepared by using several raw materials such as sodium alginate, calcium chloride, ferric chloride, ferrous chloride and graphene oxide which was prepared by Hummers' method. Then they were characterized by FT-IR, SEM, and XRD. The SEM result shows that the two kinds of beads are spherical in shape, and their surfaces are wrinkled while their interior structures are faveolate. These could greatly increase the specific surface areas with the active sites for adsorbing heavy metal ions. The X-ray diffraction results show that the molecular chains of sodium alginate intercalate into graphene oxide layer, which forms the interlayer structure, resulting in the further increase of the gap between the layers of graphene oxide. The two kinds of beads were applied to absorb the copper ions and cadmium ions in aqueous solutions, and the magnetic graphene oxide-based calcium alginate bead was also applied to the adsorption of cadmium ions in real food samples of oyster homogenate. Their adsorption characteristics were been studied and fitted with kinetic models, and the amount of the beads, the adsorption time, pH values and other conditions were been optimized. All the research data indicated that these beads had achieved very good results in the adsorption of such heavy metal ions, with the adsorption rates of 91.1% to 93.3%.

**500 NH3 vapour induced -NH2 deprotonation at gas-liquid and gas-solid interfaces: A novel step for analytical devices development for environment**

*M. Kaloo, Govt Degree College Shopian, Kashmir; B.A. Bhat, Govt Degree College, Kashmir / Chemistry; A. Hamid, Govt Degree College, Shopian Kashmir / Environmetal Science*

Molecules containing polarized N-H bonds are extensively being used as receptors for charger analytes (*usually anions*) in aprotic solvents. The ubiquitously found receptors typically utilize N-H fragments, for hydrogen bonding or proton transfer between donor (receptor) and acceptor (anion). Even though such recognition platforms have been comprehensively studied, but it is important to highlight that their sensing towards gaseous analytes are unheard of. Receptors that can respond upon interface with analyte vapours (*gas-liquid interface between receptor and analyte vapours*), could be highly valuable for forensic, environmental, industrial and explosive screening. As polarized N-H receptors are selective, development of specific receptors in this direction will be highly rewarding. Additionally, accomplishing such performances in solid phase of receptor (gas-solid interface between receptor and analyte vapours) will offer a pivotal-step towards the development of convenient and portable devices for analyte sensing in ambient air. In this work, we demonstrate an easy to synthesize (one-minute-synthesis) –$NH_2$ receptor, from diaminomalenonitrile (DAMN). The dye exhibit vapour induced -NH-H deprotonation from highly electron deficient –$NH_2$ group. For the first time, such vapour induced –NH-H interaction endorses unprecedented charge transfer (CT) across the system (*red-shift of 166 nm*). The mechanistic insight was further developed for specific ammonia vapour sensing under room temperature, *via* chromogenic readout. The operation of proton transfer signaling mechanism between receptor and vapor allocates it to completely regain original state of the molecule*via* control inputs in the form of acid vapour. Most importantly, such events were realized in the solid support of dye, impregnated on a silica surface without an chemical anchoring, signifying a pivotal-step towards development of convenient, cheap and portable analytical technology. Thus inclusion of such a receptor strategy in molecular recognition chemistry, alarms potential applications for chemical apportionment of gases in ambient air, unlikely of the existing receptors.

## Fate and Effects of Chemicals from Diffuse Sources and Stormwater – Part 2

### 501 Using passive sampling to assess PAH bioavailability from stormwater-associated sediment recontamination

*D. Athanasiou, Texas Tech University / Civil, Environmental, and Construction Engineering; D.D. Reible, M. Bejar, B. Anandha Rao, Texas Tech University / Civil and Environmental Engineering; I. Drygiannaki, Texas Tech University / Department of Civil Environmental and Construction Engineering; B. Chadwick, SPAWAR Systems Center Pacific / Environmental Sciences; G.H. Rosen, SPAWAR Systems Center / Energy and Environmental Sustainability; M. Colvin, SPAWAR Systems Center Pacific; N. Hayman, SPAWAR Systems Center Pacific / Energy and Environmental Sustainability; R. Pitt, The University of Alabama; G. Burton, University of Michigan / School for Environment and Sustainability; M. Otto, B. Steets, Geosyntec Consultants*

Urban stormwater runoff has long been identified as a major influence to the contamination of receiving water bodies and sediment. The episodic nature of storms combined with the imperviousness of urban surfaces, lead to stormwater discharges laden with high levels of solids-associated Priority Organic Pollutants (POPs). Benthic communities are one of the main receivers of such particles and are accumulators of POPs. The objective of this study was to assess the physicochemical characteristics of Polycyclic Aromatic Hydrocarbons (PAHs) found in storm runoff solids and their bioavailability to the benthos. Samples were taken during the 2015/16 and 2016/17 storm seasons at Paleta Creek at Naval Base San Diego (NBSD). The effects of the storm seasons on receiving waters were assessed by size fractioned stormwater sampling, sediment traps and cores, porewater passive samplers and in situ bioaccumulation studies with bent-nose clams (*Macoma Nasuta*) with a Sediment Ecotoxicity Assessment Ring (SEA Ring). Ex situ passive sampling and bioassays were also performed on dry weather and wet weather sediments along with additional dry weather sediment cores spiked with accumulated trap material. The stormwater sampling showed much of the PAHs were associated with large particles in runoff and led to rapid deposition and sediment recontamination in receiving waters. The bioavailability of that sediment recontamination, however, was limited as indicated by bioaccumulation in organisms and passive sampling measurements of porewater concentrations. Porewater concentrations predicted bioaccumulation in in situ bioassays with an effective bioaccumulation factor approximately equal to the octanol-water partition coefficient. Ex situ bioassays were also predicted by porewater concentration measurements if sediment trap solids were added to bioassays, suggesting the importance of stormwater deposited solids on benthic exposures and the potential misleading effects of homogenization of surficial sediments in ex situ bioassays. Sediment concentrations were not a good indicator of bioaccumulation with BSAF values

### 502 Pavement sealants--A diffuse source of PAHs and related chemicals to stormwater

*B.J. Mahler, USGS / Water Mission Area; P.C. Van Metre, USGS / Texas Water Science Center*

Pavement sealants are widely used throughout North America to protect and beautify the asphalt pavement of driveways and parking lots. Diffuse releases of chemicals associated with coal-tar-based (CT) pavement sealant—the type commonly applied to pavement in the central, southern, and northeastern U.S. and in Canada—have implications for aquatic-ecosystem health. CT sealcoat typically is 20 to 35% crude coal tar or coal-tar pitch and contains on the order of 50,000 to 100,000 mg/kg PAHs and related compounds, about 1,000 times more than alternative pavement sealant products. Since the early 2000s, research by government agencies, academic institutions, and non-governmental organizations has advanced understanding of the importance of this diffuse source of chemicals to stormwater quality and aquatic ecosystems. Research has included evaluation of rates of application, stormwater loading, air emissions, and physical wear; transport in both solid and whole-water forms; chemical profile evolution; and phototoxic effects. This presentation will synthesize the existing knowledge on CT pavement sealants and their relation to stormwater and stream contamination.

### 503 Primary sources of PAHs to Great Lakes tributaries using a multiple-lines-of-evidence approach

*A. Baldwin, USGS / Idaho Water Science Center; S.R. Corsi, USGS / Upper Midwest Water Science Center; S. Oliver, P. Lenaker, USGS / Wisconsin Water Science Center; M. Mills, USEPA / National Risk Management Research Laboratory; G. Norris, USEPA; M. Lutz, USGS / Water Resources Division*

Polycyclic aromatic hydrocarbons (PAHs) are among the most widespread and potentially toxic contaminants in Great Lakes tributaries. Urban sources of PAHs are numerous and diverse, and identifying the primary source(s) to aquatic environments can be difficult. This study used a multiple-lines-of-evidence approach to determine the likely primary source(s) of PAHs in sediment samples from 71 locations across 26 Great Lakes Basin watersheds. By using a multiple-lines-of-evidence approach, the uncertainties of each method are mitigated and common conclusions are strengthened. Diagnostic ratios, 11-compound profiles, and principal components analysis indicated that coal combustion, vehicle emissions, and coal-tar pavement sealant were the most likely primary sources of PAHs in a majority of sediment samples. Of those, coal-tar pavement sealant was found to be the most likely primary source based on mass fractions analysis. Results from land-use analysis and Positive Matrix Factorization source-receptor modeling are pending. In addition to PAH source identification, the potential toxicity to aquatic organisms was assessed by comparison to established sediment quality guidelines. The Threshold Effect Concentration was exceeded at 62% of sampling locations, and the Probable Effect Concentration and (or) the Equilibrium Partitioning Sediment Benchmark were exceeded at 41% of sampling locations.

### 504 Forensic analysis of polychlorinated biphenyls in wastewater in the Mid-Atlantic region of the USA

*S. Capozzi, University of Maryland at College Park / Environmental Science; R. Jing, University of Maryland College Park / Civil and Environmental Engineering; L.A. Rodenburg, Rutgers University / Environmental Sciences; B.V. Kjellerup, University of Maryland at College Park / Civil and Environmental Engineering*

Polychlorinated biphenyls (PCBs) are persistent, toxic and bioaccumulative pollutants. One of the few pathways via which they break down is microbial dechlorination, which has been shown to occur in sewers. Questions remain about where within sewers this process takes place and which conditions encourage dechlorination. These issues were examined using a large data set on PCBs in influent and effluents from a main and bypass outfall from a wastewater treatment facility in the Mid-Atlantic region of the USA. A data set containing 64 chromatographic peaks representing 94 PCB congeners measured in 74 whole water samples was analyzed by Positive Matrix Factorization (PMF). PMF resolved four factors and three factors represented Aroclors 1242, 1254, and 1260. The last factor represented an advanced dechlorination regime of PCBs characterized by high proportions of PCBs 4 and 19. Concentrations of the four factors were regressed against various parameters. Concentrations of dechlorination products were not correlated with total suspended solids, indicating they were mostly dissolved explaining their poor removal during the treatment process. Even though treatment generally reduces the dioxin-like toxicity of the PCB mixture, this effect might be offset by the incomplete removal of dechlorination products. Concentrations of dechlorination products were also not correlated with flow, suggesting that instead of occurring in sediment deposits that are readily scoured at high flow, dechlorination likely occurred in cohesive sediments, which have long residence times, and time to develop anaerobic conditions and harbor a slow process such as dechlorination.

**505 A Statistical Assessment of Factors Influencing PCB Concentrations Observed in Stormwater in the San Francisco Bay Area, California**

*D. Yee, San Francisco Estuary Institute; A. Gilbreath, San Francisco Estuary Institute / Watershed Program; L. McKee, San Francisco Estuary Institute / Center for Environmental Research and Sustainable Technology; J. Wu, San Francisco Estuary Institute; D. Wang, California Department of Pesticide Regulation*

The San Francisco Bay polychlorinated biphenyls (PCBs) total maximum daily load (TMDL) implementation plan calls for control measures to reduce PCB loads entering the Bay via stormwater. To support this plan, a stormwater screening monitoring program was implemented in water years (WYs) 2011, 2015, 2016, and 2017 at 71 sampling sites. At each of these sites one storm composite sample was collected. The number of samples is much smaller than the number of factors (hydrological and climatic factors as well as watershed characteristics) that can potentially influence the observed PCB concentrations and loads. In addition, there exist significant correlations among some of the factors, and the relationship between the PCB concentrations and the factors are not necessarily linear. Facing these challenges, this study developed a staged statistical procedure, utilizing methods such as partial least square regression and random forests model, to identify the factors most influencing PCB concentrations observed in stormwater. The most influential factors will be presented. These factors can be used to build mechanistic models of pollutant transport and fate, or/and rank the pollution potential of watersheds where no or few samples exist currently, allowing prioritization of areas to focus more monitoring and management effort in the future.

**506 Regional Monitoring of Biological Condition in San Francisco Bay Area Streams**

*A. Melwani, Applied Marine Sciences, Inc. / Biological Sciences; P. Randall, B. De Berry, EOA, Inc.*

In 2010, the Bay Area Stormwater Management Agencies Association (BASMAA) Regional Monitoring Coalition (RMC) embarked on a regional monitoring effort to evaluate the biological condition of wadeable streams in the San Francisco Bay region. Stream bioassessment monitoring was coordinated among six Bay Area municipal stormwater programs that conducted monitoring using standardized sampling protocols. Biological condition was assessed using four primary indicators: benthic macroinvertebrates (BMI), soft algae, diatoms, and physical habitat. During the first five years of RMC bioassessment monitoring (2012-2016), 354 randomly selected sites were sampled, representing both urban (81% of sites) and non-urban (19% of sites) land uses. The distribution of BMI and algae index scores suggests the majority of streams in the RMC sample area do not currently support healthy biological condition, with the majority of poor scores derived from urban sites. Overall, over two-thirds of the sites exhibited California Stream Condition Index (CSCI) scores in the Very Likely Altered condition class (< 0.63), while less than 10% of sites were in the Likely Intact condition class (> 0.92). Notably, both of the diatom and soft algae index scores (D18 and S2) exhibited higher condition scores than CSCI across the region. This may suggest that Bay Area streams are less degraded for algae communities, than for BMI assemblages. Random Forest (RF) models were developed to evaluate stressors associated with biological condition scores within the RMC area. The RF model of CSCI scores indicated that land use (% imperviousness) and physical habitat (% fines, % gravel, % riffle) were the most influential variables on BMI condition scores. In contrast, the RF model for D18 indicated water quality variables (conductivity, phosphorus, chloride) and physical habitat (% fines), exerted most influence on algae condition. The regional dataset generated through the collaborative program has aided stormwater managers in evaluating the ecological condition of Bay Area streams in a consistent manner, and prioritize efforts to assess how impacts can be mitigated.

**507 Biosolids-derived Dissolved Organic Matter Quality and Impact on Antimicrobial Bioavailability**

*S. Fischer, University of Maryland, College Park / Environmental Engineering; M. Gonsior, UMCES / Chesapeake Biological Laboratory; A. Hamilton, University of Maryland at College Park / Chemical Engineering; M. Ramirez, DC Water and Sewer Authority; J. Chorover, University of Arizona / Soil Water and Environmental Science; A. Torrents, University of Maryland / Civil and Environmental Engineering*

Final wastewater treatment biosolids are a widely used agricultural soil amendment because they increase nutrient concentrations of soils. Although the land-application of biosolids is a means of recycling, halogenated antimicrobials within biosolids can impact crops and terrestrial and aquatic ecosystems. Environmental dissolved organic matter (DOM) has been shown to impact the bioavailability and transport of organic compounds, such as pesticides, by enhancing solubility from solid soil matrix. While it is well-established that DOM influences the fate of organic chemicals from agricultural lands, limited work has characterized emerging contaminant interactions with DOM derived from biosolids. Furthermore, little is known about biosolids-derived DOM as a function of wastewater solids stabilization processes, including (i) anaerobically digested, (ii) aerobically digested, and (iii) limed biosolids. This work characterizes DOM from different solid-stabilization processes and probes chemical interactions with halogenated antimicrobials such as triclocarban (TCC), triclosan (TCS), and degradation product and herbicide 2,4-dichlorophenol (2,4-DCP). Biosolids-DOM has been extracted from biosolids collected from nine wastewater treatment facilities, with three facilities per stabilization method. DOM characterization by fluorescence spectroscopy revealed shifts from microbial by-product-like fluorophores in limed biosolids-DOM to greater fulvic acid or humic acid-like content in DOM derived from digested biosolids. Furthermore, high-performance size-exclusion chromatography revealed the presence of large molecular weight fractions of 1300 Da to >15,000 Da in anaerobically and aerobically digested biosolids-DOM. Limed biosolids-DOM consisted of smaller molecular weight fractions, suggesting that digestion processes could be increasing the heterogeneity of DOM. Fluorescence spectroscopy is also being applied in quenching experiments with DOM-contaminant solutions. After adding contaminant TCC and 2,4-DCP, quenched fluorescent DOM regions exhibit contrasting, pH-dependent interactions with different biosolids-DOM. Lastly, we will present results of a bacterial luminescence test applied to screen toxicity and bioavailability of TCC, TCS, and 2,4-DCP with biosolids-DOM solutions. This work evaluates molecular-scale dynamics pertinent to the diffuse release of emerging contaminants derived from biosolids application.

**508 Diffuse Sources of Fecal Indicator Bacteria in Stormwater: Does it make you sick and where is it coming from?**

*K.C. Schiff, Southern California Coastal Water Res.*

Fecal indicator bacteria (FIB) are amongst the most ubiquitous and challenging types of pollutants in urban and non-urban stormwater runoff. In California alone, there are more than 320 waterbodies with a total maximum daily load (TMDL) for FIB. FIB include microbes such as *Enterococcus* or fecal coliforms, which are not pathogens themselves, but co-occur with pathogens in sewage that can make you sick. However, FIB can also come from any warm-blooded animal (birds, wildlife, etc) confounding studies to track sources for remediation or assessing human health risk. This six-year study addresses three major management gaps in San Diego, California, a county with more than 100 million beachgoers annually (including during the rainy season), and is facing regulatory enforcement for wet weather FIB. The first management gap was an assessment of beachgoer health and a quantitative epidemiology study to measure human health risk. Surveys encompassing more than 10,000 beachgoer days were used to assess the risk of 12 different symptoms

including highly credible gastrointestinal illness. Second, more than 24 stormwater discharge samples to swimming beaches across six different wet weather events were collected and analyzed for FIB, human-specific genetic source tracking markers (HF183), and 8 different human pathogens including viruses (e.g., Norovirus I and II). Third, upstream source tracking in the adjacent urban watershed was conducted to identify the source of the human specific markers and pathogens. Twenty-six wet weather site-events were collected along the mainstem and major tributaries of the San Diego River to identify if human fecal pollution was arising from a single large source (i.e., sanitary sewer overflow, illicit connection, etc) or systemic arising from multiple locations throughout the watershed, either of which would require very different management approaches and remediation strategies.

## Effective Science Communication: Case Studies and Lessons Learned

### 509 Doumont's Three Laws of Effective Communication

*A. Goldberg Day, ARCADIS*

Jean-Luc Doumont, a recognized expert in scientific presentations, describes three general rules for effective communication. These include adapting the presentation to the audience, using a succinct message and repeating that message. He discusses how the main message needs to provide added value to the audience so they will engage with the presentation. "A message interprets the information for a specific audience and for a specific purpose (Jean-Luc Doumont)." This talk will provide details on implementing Doumont's three laws. This will include suggestions on how to adapt to your audience and take responsibility for the success of the communication. Also, in an effort for a concise presentation, examples will be given on how to maximize the signal to noise ratio, where noise is anything that could distract the audience from the message. Examples of "noise" include: speaker using repetitive gestures or sayings, excess animation on slides, laser pointers, and inconsistencies on slide. A discussion on a few common problems will also be presented. Some of these common problems include slides that are prepared for the speaker instead of the audience and slide that provide too much information, such as copy and pasting from a report. Also, in an effort to save time, slides from previous presentations can be put together without an overall cohesive objective. The goal of the presentation is to provide tools to make us all better at public speaking. The audience members should be able to take away three simple ideas that can lead to more effective presentations: easy to remember, readily applicable, and always relevant. The presentation will provide examples of messages and slides that work and ones that don't. Additionally, examples will be given on how the same message should be presented differently for two unique audiences.

### 510 A Communication Strategy to Limit the Use of Flame Retardants, PFAS, and other Chemicals Classes of Concern

*A. Blum, T. Bruton, Green Science Policy Institute*

Since 2011, the Green Science Policy Institute has developed a joint strategy with academic and NGO collaborators to more effectively communicate our peer-reviewed scientific papers. We design policy-relevant research projects and use our communication strategy to bring our scientific research results to a large audience of decision makers. Our research and communication strategy has contributed to our papers having high impact scores and many thousands of downloads. Wide communication of our papers contributed to changes in policy and purchasing for reduced use of harmful chemicals such as flame retardants and highly fluorinated chemicals or PFAS. Examples include: (1) Our 2011 and 2012 studies finding flame retardants in juvenile products and furniture, which contributed to the 2013 update of California's furniture flammability standard that increased fire safety and reduced the need for flame retardants in these products across the US. (2) Our 2015 Madrid Statement documenting a scientific consensus on the need to reduce the use of PFAS, which brought this issue to the media and a broad audience. The statement provided a scientific bases for some large consumer product manufacturers and retailers to remove PFAS from the products they manufacture and sell. (3) Our 2016 paper analyzing sources of PFAS contamination in U.S. drinking water, which has contributed to remediation and policy change. (4) Our 2017 paper on PFAS in food contact materials, which educated the supply chain and has contributed to policy change and a decreased use of PFAS. Here is an overview of our communications strategy which we will discuss in more detail: Select a research topic to support policy in public interest. Collaborate with expert authors from multiple institutions. Once a manuscript is accepted, work with the journal to select a release date several weeks in the future for maximum impact. Compose a press release in accessible language with a "hook" to attract attention. Query journalists and then share the press release and embargoed paper. Educate journalists on the science and establish relationships. We encourage other scientists to consider such a communications strategy to increase the impact of their research publications.

### 511 The potential and challenges of photography in science communication

*A. Bonisoli Alquati, California State Polytechnic University, Pomona / Department of Biological Sciences*

Communication through images is arguably more prevalent than ever in our culture, largely thanks to its relatability and prevalence in social media. Journalism, including environmental journalism, has been increasingly harnessing the power of images to illustrate news and create engagement. On the contrary, the use of images in science communication by scientists is only in its infancy. I argue here that photography provides a powerful tool for scientists to effectively communicate their research. This is particularly true in the most recent phase of science communication, which is defined in terms of public engagement, rather than as a tool for spreading scientific literacy. Photographs can also help scientists solve some of the challenges that they typically face when involved in science communication, precisely because of their training. Many scientists find it difficult to summarize their findings without relying on extensive details and on the use of technical jargon, two common expressions of the so-called 'curse of too much knowledge'. Visual communication provides a way out of such difficulties, being relatable, memorable and concise – all of which are features praised by science communicators as effective ways to engage non-scientists. Photographs can also be distributed without modification, allowing a message to faithfully spread, and can be combined to narrate stories and convey powerful messages. Yet, as promising as all of this sounds, the use of photography in science communication comes with its own challenges. For example, contrary to the common concept of photography as an objective way of portraying reality, photographs are the result of technical and semantic choices, which reflect the subject taking them. The use of images in science communication requires more than the ability to craft images – it entails thinking in terms of the meaning and implications of those images. In addition, an effective use of photography in science communication also requires scientists to become adept at storytelling through images, which comes with its own series of rules and challenges. All scientists can learn those rules, but there is a long road ahead.

### 512 ScienceBites: A Multidisciplinary Online Community for Early-Career Scientist Writers

*C.A. McDonough, Colorado School of Mines / Civil and Environmental Eng*

The "Bites" family of blogs (astrobites.org, oceanbites.org, envirobites.org, chembites.org, and many others) provide a platform to connect early-career scientists with non-expert audiences by sharing compelling, bite-sized research summaries in a wide variety of scientific fields. Until recently, the Bites Sites have existed as an ad-hoc collective, with each site run independently by rotating teams of graduate-student and early-career scientist volunteers. ScienceBites is a new collaborative network run by representatives from each of these sites. We are bringing the "Bites Sites" together to work toward our common goals and increase visibility of all of the different Bites Sites among our readership. Early career scientists (graduate students and postdoctoral researchers) in STEM fields are an untapped source of very enthusiastic science writers, eager to share their research stories with the broader public. However, they often lack confidence in communicating with broader audiences, and they may have difficulty finding training resources to guide them in honing messages for non-experts, or platforms where they can publish their non-scientific writing. At the ScienceBites blogs, these scientist writers regularly publish articles translating recent research articles in their field into engaging blog posts written for broad audiences, with undergraduate students specifically in mind. They also edit posts by other writers. ScienceBites is working to form a centralized online hub to aggregate work from early-career scientists writing at many different Bites Sites, and to provide support and advice to students looking to start new Bites Sites in additional disciplines. When our website is launched, we also plan to disseminate free online resources that will help to train new Bites writers and other science writers to communicate effectively with non-experts. Here, we will introduce SETAC attendees to our growing network of science blogs, which currently features 14 websites in 3 languages. We will also summarize what we have learned thus far about creating engaging science blogs, outline our future plans to grow ScienceBites, and provide information for any graduate students interested in joining an existing site, or starting a new one!

**513 Indirect Effects of Fishing Regulations on Human Mercury Exposure Pathways**

*J. Collins, A. Miano, AECOM; R.G. Stahl, E.I. DuPont de Nemours and Company / Corp Remediation; M. Liberati, E. I. du Pont de Nemours and Company*

Fish consumption advisories have been in place for more than four decades for a 24-mile reach of the South River, beginning at the former DuPont Waynesboro Virginia facility due to legacy mercury. There is currently a consumption ban in effect for all fish species with the exception of stocked trout, which are routinely monitored for total mercury (THg) concentrations by the Virginia Department of Environmental Quality and are considered safe to eat. The Virginia Department of Game and Inland Fisheries recently modified the trout fishing regulations for a portion of the South River in the City of Waynesboro to a Catch and Release (C&R) fishery to enhance the quality of the fishery. Previously, this reach was managed as a Delayed Harvest trout fishery, which permitted the harvesting of stocked trout from June 1st through September 30th. The change in fishing regulations to a C&R trout fishery may influence exposure durations of stocked trout, which may continue to accumulate mercury over time. A potential consequence of this change is that it creates the opportunity for anglers to illegally harvest and consume hold-over trout (i.e. stocked trout that survive through the summer months) in the C&R regulated area as well as legally consume hold-over trout that have migrated to other reaches of the river. To understand the potential impact of a longer exposure period of trout to bioavailable mercury in the South River, THg concentrations in hold-over, stocked trout were compared to the Virginia surface water quality criteria of 0.3 mg/kg THg in fish tissue. This presentation will provide a brief history of the legacy mercury contamination on the South River and the risk-management challenges associated with competing stakeholder goals. It will focus on how changes to fishing regulations may alter potential human exposure pathways, as well as the approach used to evaluate, document, and communicate potential changes to the site-specific risk/exposure paradigm.

**514 Rapid deployment of passive sampling wristbands in response to Hurricane Harvey: Community engagement and reporting**

*P. Hoffman, H. Dixon, Oregon State University / Environmental and Molecular Toxicology; D. Rohlman, Oregon State University / Environmental Health Sciences Center; L. Tidwell, K.A. Anderson, Oregon State University / Environmental and Molecular Toxicology*

Hurricane Harvey made initial landfall at San Jose Island TX, on August 25,2017. In some areas Harvey produced over 50 inches of rain, causing immediately flooding of low-lying terrain. On September 2nd several dams in the area released excess water, expanding the scope and duration of flooding. Thirteen Superfund sites were flooded and millions of pounds of hazardous chemicals were released. Multiple fires, explosions and chemical spills were reported. Researchers at Oregon State University (OSU) have been preparing for disaster research for several years, having in place an Institutional Review Board (IRB) approved 'Disaster IRB.' This IRB allowed OSU researchers to deploy chemical sampling technology quickly, with appropriate controls to ensure participants were safe and personal information was confidential. Immediately after safety in the area was ensured, contacts were established with collaborators in the Houston area. Equipped with the approved IRB and previously assembled 'go bags', developed for rapid field deployments, OSU personnel traveled to Texas. On September 20th, the OSU team conducted a training session with collaborators from multiple universities and enrolled volunteers from the highly-impacted Highlands, Baytown, Crosby and surrounding areas of Houston in a study in which participants wore passive-sampling silicone wristbands for one week during their Harvey clean-up process. Because of their small size, portability and ease-of-use, silicone wristbands are particularly suitable for post-disaster chemical sampling. Many participants were actively involved in clean-up during the sampling period. After one week, participants packaged and mailed their wristbands back to OSU. Even in the aftermath of Harvey, compliance was 85%, illustrating the approachability of this technology. Each wristband was analyzed for 1,529 chemicals, generating over 40,000 chemical data points for this initial study. In June of 2018, OSU personnel returned to Houston to communicate the results of the wristband analysis to participants. On average, participants had the highest number of chemical detections per wristband of any cohort examined to date. Additionally, OSU provided 200 wristbands to collaborators from Baylor School of Medicine and UTHealth School of Public Health for use in additional Harvey-related chemical exposure studies in which the initial disaster response chemical data will be paired with a follow-up non-disaster sampling campaign.

**515 Plastic bag bans in South Carolina: Science communication from grant proposal to informing public policy**

*A.D. Gray, University of North Carolina at Greensboro / Biology; J. Weinstein, The Citadel, Military College of South Carolina / Biology*

In 2014, the SC Sea Grant Consortium funded a proposal to investigate the sources, fate, and effects of plastic and microplastic pollution in Charleston Harbor, SC. As part of that proposal, the principal investigators (Drs. John Weinstein and Steve Klaine) proposed an outreach component that included communicating the results to stakeholders, the scientific community, and the general public. The results of this study were presented to local environmental groups (e.g. Audubon Society, Sierra Club), natural resource managers, and the scientific community. The principal investigators also worked closely with their respective on-campus Office of Communications/External Affairs to share the results with the general public through local media. Lessons learned from working with communication experts will be shared including the importance of using effective talking points and practice interviews. Communication strategies such as the timing of press releases, working closely with the media, and developing a "hook" for the story will also be shared. These outreach efforts, in part, led to several towns in coastal South Carolina banning single-use plastic bags and foam containers. Subsequently, these local bag bans resulted in the creation of House Bill 3529, also known as the Anti-Home Rule Act, which is currently being debated in the SC State Legislature. This act would ban local communities from passing bans on single-use plastics. While the primary intent of this funded research was to investigate plastic pollution and communicate our findings to stakeholders and the scientific community, through effective strategies, we were also able to communicate these findings to the general public. The impact of our outreach efforts far exceeded our initial expectations. This case study provides a compelling example of how effectively communicating science can influence public policy, and it underscores the value in making scientific results accessible to the public.

**516 Effective Science Communication – A Panel Discussion**

*J. Clarkson, Louisiana Department of Natural Resources; S. Sager, Arcadis U.S., Inc.; L. Paulik, Maul Foster & Alongi, Inc. / Environmental and Molecular Toxicology; A. Bonisoli Alquati, California State Polytechnic University, Pomona / Department of Biological Sciences; W.J. Berry, USEPA / Atlantic Ecology Division / ORD / NHEERL*

Examples of both successful and unsuccessful communication of scientific issues can provide opportunities to develop clear strategies for talking to stakeholders. Communicating science on topics such as risk assessment, risk management and policy development requires interaction between scientists and stakeholders. Government agencies, industries, and scientists have long employed structural approaches to communicate science, risk, and policy to interested parties. Risk assessment, adaptive management, structured decision-making and translational science may use different terminology and employ slightly different approaches, but they all stress the importance of meaningful communication with stakeholders before, during, and after projects. However, many scientists tasked with conveying the information remain uncomfortable in the role of science or risk communicators. The importance of effectively communicating with stakeholders is therefore often overlooked and risk communication remains one of the most underused tools for environmental management. This panel discussion will engage the audience and all the speakers for the session in a two-way conversation designed to highlight effective risk communication strategies as tools for use by science and risk communicators. The co-chairs for the session will moderate the discussion. Each presenter will provide a single summary slide to the moderators, who will review and collate the information. The combined summary will be used as a starting point for discussion and for drawing questions and comments from the audience. The moderators will also create a list of questions and comments for the panel, to ensure a robust and lively discussion is presented. If needed, the panel can respond to any questions that were not addressed during the individual presentations due to time constraints. Through our presentations and panel discussion, we will highlight ways to make science more accessible and useful to stakeholders. Ultimately this will promote more useful science, and greater public awareness of the importance of science.

## Micro- and Nanoplastic Methods for Environment Media

**517 Are Microplastic Measurements Comparable and Do They Reflect Reality?**

*W. Cowger, J. Guilinger, A. Gray, University of California Riverside / Environmental Science*

Accurately monitoring microplastic pollution in aquatic systems faces a number of challenges, from the technical details of sample collection and laboratory preparation, to the very metrics used to quantify abundance and character. Surface grab sampling is a common method of monitoring microplastics in rivers and streams. Utilizing previously published field data we investigated microplastic concentration profiles with hydrodynamic models. These models indicate that surface sampling can result in drastic over or under prediction of plastic abundance, depending on plastic type, size, and concentration. In the laboratory, density separation is a primary step for extraction of microplastics from various media, especially sediments and turbid waters. Average losses reported in spiked samples during density separation across laboratories range from 30-70%. We have found that even small changes in protocols can result in the difference between detection and non-detection in low concentration samples. Furthermore, count alone, the typical metric for measuring plastic concentration, does not provide the information needed for understanding the mass flux of microplastics and associated contaminants, and ultimately for effective plastic pollution management. We argue that morphometric information on microplastic particles is required for the estimation of useful metrics such as surface area, volume, and mass. Ultimately, standardization of monitoring, processing and measurement techniques will advance the comparability of results between laboratories, inform the assessment of environmental impacts, and develop effective management strategies.

**518 Recovery of microplastics from fine grain sediment with a common density separation technique using different agitation methods**

*S. Kell, College of Charleston / Grice Marine Laboratory; H. Mazur, The College of Charleston / Department of Geology; B. Beckingham, College of Charleston / Environmental Geosciences; J. Weinstein, The Citadel, Military College of South Carolina / Biology*

The most widely used method to extract microplastics (MPs) from sediment is a density separation technique described by Thompson et al. (2004) that uses a concentrated NaCl solution (1.2 g/cm$^3$) to float or suspend MPs so they can be decanted or filtered. This may be repeated multiple times to increase recovery, or used with other steps, such as chemical digestion by wet peroxide oxidation, to separate MPs from sediment. A majority of studies using a NaCl density separation have sampled coarse grain sediment, with recovery rates reported for spiked MPs. The objective of the present study was to test the effect of different mixing methods on the recovery rates of native MPs in fine grain sediment with high organic matter, which may bind MPs and impede separation. In addition, we focused on recovery rates of tire wear particles (TWP) which can be considered as an elastomer microplastic and have likely been under-reported in microplastic surveys in the U.S. We tested four mixing techniques (stirring, shaking, sonication and shaking/sonication) on 200 g of stormwater pond sediment and 2 L of solution in 4 L jars and repeated sequential extractions ten times. The supernatant was decanted through nested sieves (63, 150 and 500 mm) and treated to a mild hydrogen peroxide digestion (< 10% $H_2O_2$, 20°C). Microplastics were counted using optical microscopy. After the first extraction, more MPs were found in the order: shake > stir > shake/sonicate >> sonicate only. After four sequential extractions, method recoveries converged at 82.2 ± 1.8% (as % of total MPs after 10 extractions). Total microplastics extracted from the stormwater pond sediment sample (methods pooled, N=4) after 10 extractions was 12.0 ± 2.0 MP/g wet wt. On average, TWP comprised 75% of the total microplastics recovered; 95.8% were captured using shaking with four sequential extractions. We hypothesize that adherence to glassware, sweep flocculation during settling, and/or inability of the mixing methods tested to separate native MPs from mineral or organic agglomerations act to challenge recovery. In addition, we found tire wear particles are not compatible with wet peroxide oxidation conditions typically employed, and a milder treatment is required. This study highlights stormwater ponds as potential MP hotspots, as well as the need for testing and reporting of recovery rates of native MPs and further optimization of this low-cost and eco-friendly method for fine grained sediments.

**519 Magnetic Extraction of Microplastics from Environmental Samples**

*J. Grbic, University of Toronto / Ecology and Evolutionary Biology; B. Nguyen, University of Toronto / Department of Mechanical and Industrial Engineering; E. Guo, University of Toronto / Ecology and Evolutionary Biology; J.B. You, D. Sinton, University of Toronto / Department of Mechanical and Industrial Engineering; C.M. Rochman, University of Toronto*

Different methods to extract microplastics from environmental samples have been well researched, with methods like density separation, size separation, and chemical digestion emerging as the standard means of extraction. Still, small microplastics are often lost during the extraction process, and thus it is worth exploring complementary methods. We tested the ability of extracting microplastic particles from an environmental matrix by hydrophobicity. This was tested by surface modifying iron nanoparticles with a silane with a long hydrocarbon tail, and mixing them

into a sample where they bind to plastics via hydrophobic interaction. We then tested the efficacy of using a magnet to extract the plastics from the sample. We tested the method by spiking and recovering polyethylene and polystyrene in the size ranges of 10 – 20µm and had an average recovery of 92%. Additionally, we spiked and recovered polyethylene, polystyrene, polyurethane, polyvinyl chloride, and polypropylene in the size ranges of 300µm – 1mm and 1 – 5mm. The results for the 300µm – 1mm size range were an average recovery of 84% in reverse osmosis water and 78% in sediment from San Francisco Bay. For the 1– 5mm microplastics, the average recovery was 97% in reverse osmosis water. Overall, our novel method has relatively high recovery rates across different size ranges and media. Although further research can be done to work out some issues, such as the brute force of the magnet fragmenting microplastics, we believe the magnetic extraction procedure may provide a nice compliment to existing methods.

**520 Measurement of Microplastics using Pulsed Ultrasonic Extraction and Complementary Micro-spectroscopy Analyses**

*J. Wagner, S. Ghosal, Z. Wang, S. Wall, California Dept. of Public Health / Environmental Health Laboratory; M.B. Murphy, AAAS; H. Allen, W. Robberson, USEPA Region 9 / Superfund Emergency Response; A. Cook, USEPA Region 9; G. Robiou, E. Laird, USEPA / Office of Water; L. Stahl, USEPA / Office of Water / Office of Science and Technology*

Separation and characterization of microplastics < 1 mm in biological and environmental samples presents numerous analytical challenges. This work presents alternative sample extraction and analysis techniques used to identify microplastics as small as 15 um and address previously noted issues with other methods. Extraction methods that remove biomass matrices using aggressive chemicals can be problematic for the smallest microplastics, sometimes eroding their surfaces and creating reaction products that interfere with analyses. The current work instead utilizes ultrapure water and pulsed ultrasonic extraction to separate plastics from biomass without dissolving either, thereby preserving plastic surface characteristics, any adsorbed chemical species, and associated biota and ecological pathway information. This method was used to successfully separate microplastics from the stomachs of various species of freshwater and marine fish. Extracted particles were identified and characterized in terms of type, size, and morphology using complementary optical microscopy, scanning electron microscopy plus energy-dispersive x-ray spectroscopy (SEM/EDS), Fourier Transform infrared (FTIR) micro-spectroscopy, and Raman micro-spectroscopy (RMS). After optical and SEM/EDS screening, FTIR and RMS were used to identify specific plastic types. Shell pieces were identified in many fish stomachs that resembled microplastics, as were brittle, degraded plastics that were shattered like shells. Studies that rely on optical microscopy alone are thus prone to false positives and false negatives. Current progress and challenges for automation and optimization of these extraction and identification methods are discussed for various matrices, including method modifications for large freshwater fish, and separate analyses of prey fish inside larger fish stomachs.

**521 Method for Quantifying Microplastic Generation Rates from Various Plastics**

*J. Sipe, Duke University / Civil and Environmental Engineering; M. Wiesner, Duke University; N. Bossa, Duke University / Department of Civil and Environmental Engineering*

Microplastics have become an emerging new pollutant of rising concern due to exponential growth of plastic use in consumer products. Most microplastic pollution comes from the breakdown of larger scale plastics leading to the need of knowing how plastics behave in the environment. One way to study how microplastics are created in the environment is by using mechanical abrasion. A? custom abrasion machine has been built with novel features that provides data to calculate both generation rate and power?input. The generation rate of microplastics through abrasion across a variety of plastics ranging from biodegradable plastics ?to more persistent plastics in the environment (with and without nano?fillers) will be tested. These tests will determine the generation rate of ?microplastics from each plastic type using a constant power input and to ?identify plastic properties that drive their fragmentation. It is predicted that the plastics that fail faster under mechanical strength testing will produce more microplastics during abrasion and nano additives that add to the strength of the plastic material will produces less microplastics during abrasion. Currently, Polylactic acid (PLA), polyethylene glycol (PETG) and polycarbonate (PC) plastics have been tested using tensile tests and abrasion tests to calculate power input and abrasion rate. If 400 Joules of power is applied the abrasion rate is 110 g/m$^2$/min for PETG and 40 g/m$^2$/min for PC. This shows a correlation with PC being a stronger plastic than PETG. Results for the following plastics are also underway: thermoplastic rubbers, high impact polystyrene (HIPS) and polyvinyl chloride (PVC). The first overall power input and rate of generation to predict mass released of each type of plastic into the environment. Overall, this project will help comprehend and provide instrumental initial data to understand generation rates of microplastics from larger scale plastics and reduce microplastic pollution.

**522 Plastics in the salad? A first study for uptake and toxicity of nanoplastics in Lactuca sativa**

*A. de Souza Machado, Freie Universität Berlin / Institute of Biology; E. Faltin, J.B. Bachelier, Freie Universität Berlin; W. Kloas, Leibniz-Institute of Freshwater Ecology and Inland Fisheries; M.C. Rillig, Freie Universität Berlin*

Microplastic pollution is taking place in global ecosystems. However, there is a lack of toxicological information of the most reactive fraction of this novel stressor: the nanoplastics. This hampers risk assessments for environmental exposure, trophic transfer, and human health. We grew seedlings of *Lactuca sativa* (lettuce) for ~ 2 weeks in Hoagland hydroponic solution (control conditions) and then exposed individual plants to control conditions or to 6 different polystyrene nanoparticles encapsulated with red or blue fluorescent dye. The nanoplastic treatments were a factorial combination of 3 surface terminations (COOH, plain, and $NH_3$), 2 sizes (50 and 100 nm), and 2 concentrations (0.05 and 0.1 mg mL$^{-1}$). Plant evapotranspiration was monitored throughout the exposure. Seedlings (N=6) were harvested at 4 h, 8 h, 12 h, 24 h, 48 h, and 96 h of nanoplastic exposure, when the roots were removed from exposure media and washed in MiliQ water (10 min sonication, 35 kHz , 640 W, 10 mL). This root-wash and the hydroponic media were frozen. Plant parts (roots, shoots, or leaves) were separated, quickly freeze-dried and stored at – 80 °C. All plant tissues were later homogenized in phosphate buffer (pH 7.01, 0.1 mM). Fluorescence targeting the nanoplastic dyes was measured in the root-wash solution, hydroponic exposure media, and plant tissues. We quantified protein concentration and antioxidant capacity in plant tissues. All the nanoplastic types significantly affected plant physiology, with magnitude depending on particle properties and exposure concentration. The $NH_3$termination with 50 nm triggered the strongest effects on evapotranspiration and plant fresh weight. Generally, fluorescence decreased from exposure media to root-wash, root tissue, and then to other plant parts suggesting uptake that followed common temporal uptake patterns. However, this is not conclusive as the increase in fluorescence of shoots and leaves might be due to pigment changes of plastic-exposed plants. Also, confocal microscopy confirmed that most root fluorescence was due to nanoplastics strongly interacting with roots surfaces. Nevertheless, physiological changes in lettuce biomass, tissue protein, and antioxidant response were observed. Further research is needed to conclude whether this common dietary species would uptake plastics. However, the effects and their association with root fluorescence suggest that the idea of nanoplastics arriving at the salad plate cannot be discarded.

**523 Effects of waterborne and dietary exposures of nanoplastics in zebrafish: Maternal transfer, mitochondrial bioenergetics, and interaction with PAHs**

*R. Trevisan, Duke University / Nicholas School of the Environment; J.A. Pitt, State University of New York College of Environmental Science and Forestry / Department of Chemistry; C. Voy, Duke University / Nicholas School of the Environment; S. Chen, North Carolina School of Science and Mathematics; O. Saleh, R.T. Di Giulio, Duke University / Nicholas School of the Environment*

Plastics are ubiquitous anthropogenic contaminants, including particles down to the nano-scale that are a growing concern in aquatic environments. The hazard of macroplastics is well documented, but micro and nanoscale particles remain relatively understudied. We have used zebrafish and polystyrene nanoparticles (PSNp) to understand the uptake and effects of nanoplastics on aquatic species. Initial experiments with embryos indicated that exposure to waterborne PSNp (0.1 – 10 ppm) caused early accumulation in the yolk sac, followed by the head, heart, and digestive organs. Despite such biodistribution, only minor signs of toxicity were detected, such as bradycardia and hypolocomotor activity. Further experiments also indicated that dietary exposure of adults to PSNp (as 10% of food weight) for one week did not affect their reproductive success, but PSNp were maternally transferred to the offspring. Both the adults and offspring had signs of impaired antioxidant system function, in addition to minor effects on the offspring embryonic development. Lastly, the interaction of PSNp on PAH toxicity was assessed in embryonic zebrafish. While embryos exposed to an environmental mixture of PAHs had signs of teratogenicity (pericardial edema and heart malformations) and impaired angiogenesis, once again waterborne PSNp exposure alone (0.1 – 10 ppm) did not cause significant effects on such parameters. Interestingly, PSNp co-exposure partially blocked these effects, which was correlated to reduced PAH uptake. The high surface area and hydrophobicity of nanoplastis likely facilitate PAH sorption, decreasing PAH bioavailability in our exposure condition. PAH sorption to PSNp was further investigated by spiking PSNp with a mixture of PAHs for one week, followed by exposure of zebrafish embryos to 1 ppm of spiked PSNp. PAH uptake and EROD induction were evident, but no signs of developmental toxicity were detected. In both experiments, PSNp seemed to be a biologically inert material, but they caused significant effects on mitochondrial function at larval stages: virgin PSNp (10 ppm) strongly decrease ATP linked mitochondrial respiration while PAH spiked PSNp (1 ppm) decreased mitochondrial spare capacity. Taken together, these data indicate that nanoplastics can: (i) accumulate via direct waterborne exposure, food chain and parental transfer; (ii) impair locomotor activity and mitochondrial bioenergetics; (iii) interact and modulate the toxicity of organic contaminants.

**524 An evaluation of the challenges and limitations associated with aquatic toxicity and bioaccumulation studies for manufactured particulate substances**

*T. Gouin, TG Environmental Research / Safety and Environmental Assurance Centre; E. Salinas, BASF SE / Eperimental Toxicology and Ecology; K.K. Coady, The Dow Chemical Company / Toxicology Environmental Research and Consulting; D. Lyon, Shell Oil Co. / Shell Health Risk Science Team; J. Sergent, SOLVAY / HSE; P. Hopp, BASF Personal Care and Nutrition GmbH; M. Leonard, L'Oréal SA / Recherche Environnementale*

The observations of physical effects in a variety of standardized and non-standardized ecotoxicological aquatic test systems in relation to exposure to nano-materials and microplastics challenges our interpretation of the potential risks associated with the use of such materials. There are a large number of stakeholders that have an interest in the results produced from toxicity tests. This results in a highly dynamic scenario which might limit the positioning and development of scientific test systems aimed at quantifying the differences between the intrinsic chemical toxicity mediated by molecular interaction between dissolved substances and biological receptors and physical effects associated with what is often mistermed 'particle-toxicity'. The example of microplastics is characteristic of a fast-moving issue that is likely to be regulated using hazard-based or precautionary approaches. The adoption of hazard-based regulatory instruments, however, should act as a warning, in that they impede the development of scientific tools aimed at assessing toxicity and risk for a wide range of both naturally and synthetically derived particulate materials. In this presentation, we demonstrate the importance of applying mechanistic understanding of the processes that influence exposure and effects of particles, differentiating between intrinsic chemical toxicity and physical effects. A key component in the development of mechanistic understanding is an appreciation of accurately defining the material under investigation, including the physical characteristics of size, shape, density, surface charge, as well as an understanding of its chemical nature. Based on an appreciation of the complex relationship between intrinsic and extrinsic properties that can occur within a test system, standardized approaches for creating and maintaining dispersions of particles and poorly soluble materials are urgently needed. In an effort to stimulate constructive dialogue between key stakeholders, a list of recommendations are reported for developing/interpreting aquatic toxicity tests with particles or poorly soluble substances that cause physical effects in test systems. These recommendations are meant for use beyond addressing nanomaterial or microplastic toxicity, but should be considered when encountering any material or chemical for which a physical effect is possible.

## Mechanistic Ecotoxicology: Bridging the Gap from Investigative to Regulatory Ecotoxicology

**525 Opportunities and challenges in the use of mechanistic ecotoxicology in ecological risk assessment**

*J.P. Staveley, E. Freeman, Exponent*

The measures of effect that are of concern in ecological risk assessment are those that relate to population-relevant endpoints (typically survival, growth and reproduction) because the goal is generally the protection of populations, not individuals. To characterize ecological effects of chemicals, data have historically been generated on individual species in laboratory exposures. We have expanded the field of ecotoxicology "up and out" in an attempt to obtain more environmental realism by, for example, looking at effects on multiple species in mesocosm studies. We have also expanded the field "down and in" to try to understand effects at sub-individual levels of biological organization and to find means to extrapolate this information to whole organisms and beyond. This is the essence of the Adverse Outcome Pathway (AOP) concept, which provides a useful construct for linking biological changes (key events) at the molecular, cellular, or tissue level, through processes at successively higher levels of biological organization to an observable adverse outcome, which is a biological change considered relevant for risk assessment. The development of High Throughput Screening (HTS) tests (in silico, in vitro, and small scale in vivo tests) offers promise in identification of key events. Similarly, information on toxicokinetics (TK) and toxicodynamics (TD) can explain the pattern of toxic effects over time by simulating the underlying processes, and can help expand our ability to characterize effects in individuals as well as at other levels of biological organization. Applications for these types of tools include chemical prioritization, development of QSARs, understanding differences in species sensitivities, read-across from one species to others, use in intelligent testing strategies, and assessing time-dependent toxicity or effects of fluctuating exposures. These tools thus hold the promise of reducing time, money, animal testing, and ultimately improving risk assessments. However, there are numerous challenges in building confidence that mechanistic ecotoxicology and HTS methods can ultimately be fully used in regulatory risk assessments to evaluate population-level impacts for ecological receptors. Distinguishing effects that may be adaptive or secondary effects from those that are adverse or primary effects, and translating these to outcomes for individuals and ultimately populations, will likely require a diverse set of tools and holistic thinking.

**526 Performance-Based Measures on Which EPA Relies in Determining the Utility New Approach Methodologies Using Defined Acceptance Criteria**

*E. Odenkirchen, USEPA HQ / Office of Pesticide Programs / Environmental Fate and Effects Division*

The Office of Pesticide Programs of the United States Environmental Protection Agency is committed to exploring new approach methodologies (NAMs) to prioritize testing, evaluate surrogacy, and establish effects endpoints for ecological risk assessment, provided the utilization of a NAM does not compromise the quality of the risk assessment process. This presentation outlines the background use, guiding principles and points to consider in establishing relevancy, reliability and confidence of NAMS for consideration in the ecological risk assessment process.

**527 Cross-species comparative analysis of Fish Short Term Reproduction Assay (FSTRA) data for the Endocrine Disruptor Screening Program (EDSP)**

*S.G. Lynn, USEPA / Endocrine Disruptor Screening Program; R.J. Bever, USEPA / Office of Science Coordination and Policy; K.L. Hamernik, A. Kamel, S.R. Matten, USEPA / Office of Science Coordination and Policy*

The US Environmental Protection Agency (EPA) established the EDSP to screen for chemicals that have the potential for adverse effects on the estrogen, androgen or thyroid systems. EDSP utilizes an 11 assay Tier 1 screening battery, which includes the FSTRA. The FSTRA is a 21-day aquatic exposure assay designed to measure fish reproductive success and other, potentially mechanistic, endpoints. The EPA guideline (OPPTS 890.1350) specifies the use of fathead minnows (FHM) while the OECD guideline (TG 229) also allows the use of Japanese medaka (JM) or zebrafish (ZF). The EPA is investigating cross-species sensitivity and variability of chemical toxicity testing data to facilitate assessment of endocrine bioactivity across wildlife species. FSTRA studies were conducted using all three species and survival, fecundity, plasma vitellogenin (VTG) concentrations (FHM & ZF), and liver mRNA (*vtg*) expression (JM & ZF) were measured along with other endpoints. Four (4) chemicals were tested: bisphenol A (BPA), 2-ethylhexyl-4-hydroxybenzoate (2-EHHB), triclosan (TCS), and tetrabromobisphenol A (TBBPA). These are well studied chemicals with ToxCast estrogen receptor (ER) bioactivity data available. These studies were conducted across multiple labs and inter-lab variability for control fecundity and body weight will be presented. Preliminary analyses indicate only TCS and BPA had significant effects on survival at the highest concentrations tested (based on measured concentrations) for JM (179 µg/L) and FHM (1300 µg/L), respectively. LOECs (µg/L) for fecundity are: BPA – JM (< 7.29), FHM (460), ZF (830); 2-EHHB – JM (< 2.98), ZF (42.2), FHM (>110); TCS – ZF (1.3), FHM (14), JM (57.5); and TBBPA – ZF (>276), FHM (366), JM (>1970). BPA and TCS show a greater than 10X difference in fecundity LOECs between the most sensitive and least sensitive species, which vary by chemical. Both BPA and 2-EHHB produced responses in VTG and/or *vtg* in all three species. BPA produced a response in male liver *vtg* at a lower concentration than fecundity only in ZF (< 21 µg/L). While 2-EHHB produced a response in male plasma VTG at a lower concentration than fecundity only in FHM (53 µg/L). BPA and 2-EHHB have reported ToxCast ER bioactivity scores of 0.45 and 0.37, respectively. Results support an estrogenic mode-of-action for BPA and 2-EHHB, but also demonstrate species-specific differential sensitivities across the four chemicals. *This abstract does not necessarily represent USEPA policy.*

**528 Response-response versus dose-response: Research to enhance the utility of adverse outcome pathways for regulatory decision-making**

*D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory*

The adverse outcome pathway (AOP) framework was designed to aid the interpretation and extrapolation of mechanistic ecotoxicology data to outcomes of regulatory significance, typically measured at higher levels of biological organization. To date, AOPs have been used to support screening and prioritization of chemicals for further testing, guide more hypothesis-driven and tiered approaches to testing, inform the development of alternative assays, and help organize and interpret diverse toxicological data sets. However, many regulatory applications require the ability to generate quantitative estimates, bounded by some measure of uncertainty, of the probability or severity of an adverse outcome. Ideally AOPs could be used to help derive those quantitative estimates of apical effect based on non-traditional or mechanistic data obtained from so called "new approach methodologies" (NAM) or "alternative assays". However, most AOPs currently lack the kind of quantitative understanding required to facilitate quantitative estimation of biological effect thresholds. In part, this stems from toxicology's traditional focus on dose-response or concentration-response. Development of the models and understanding needed to support quantitative translation of NAM-derived data to estimated apical effects requires a shift in perspective in toxicological research and experimental design, away a sole focus on empirical characterization of dose-response, and toward the characterization of response-response relationships. This presentation will define and provide examples of response-response relationships and illustrate how they aid quantitative extrapolation along an AOP framework. Additionally, it will discuss the types of experimental designs that could be incorporated into mechanistic ecotoxicology research to better define response-response. Improved definition of response-response relationships is expected to enhance the utility of AOPs, and in turn expand the use of mechanistic data in regulatory decision-making. *The contents of this abstract neither constitute, nor necessarily reflect USEPA policy.*

**529 Role of in silico approaches in regulatory sciences: Mechanistic perspectives**

*V. Forbes, University of Minnesota / Ecology, Evolution & Behavior*

Much of the information used to assess the ecological risks of chemicals is gathered from standardized tests conducted under controlled laboratory conditions that measure individual organism responses in a handful of species. Growing pressures to reduce the use of vertebrates in toxicity testing, combined with methodological developments in high-throughput screening and in vitro technologies are encouraging new approaches to risk assessment. The Adverse Outcome Pathway (AOP) is being used as a conceptual framework to logically connect biochemical responses to chemicals, measured in vitro, to outcomes of relevance for risk assessment. Whereas an AOP framework can facilitate mechanistic insights into chemical impacts across different levels of biological organization, to be useful for estimating risk in a regulatory context, AOPs need to move beyond conceptual descriptors to quantitative, mechanistic models whose nonlinearities, feedbacks and uncertainties can be captured and communicated. In silico approaches, i.e., models, informed by relevant data, are needed to do this. Despite an extensive and growing body of literature documenting how mechanistic models can add value to ecological risk assessment, few have so far been used in a regulatory context. I will discuss reasons for this as well as some ongoing initiatives to address the concerns of the regulatory community and facilitate the implementation of in silio approaches in the future.

**530 Ecological models for pesticide risk assessment: How to balance complexity, uncertainty and practicality**

*P. Thorbek, BASF SE / Environmetal Safety*

Ecological risk assessments of pesticides are typically carried out by considering exposure estimated by e-fate modelling and effects estimated by laboratory experiments for standard species. However, with ecological models becoming more common risk refinement tools, several other factors are typically included in the risk assessment; e.g. life history, dispersal, population resilience, multiple stressors, landscape structure and temporal dynamics. This raises challenges for both registrants who have to identify which models can do this well and regulators who have to assess whether the models have been adequately designed, parameterised and applied. Using examples from bee modelling, model complexity, uncertainty analysis, good modelling practice and regulatory acceptance are discussed. The science of effect modelling is developing fast, but for routine use in regulatory risk assessments practicalities also need to be considered. Recommendations for model standardisation and development of baseline scenarios are given.

**531 A Chemical Prioritization Approach Based on EU Guidance for the Identification of Endocrine Disruptors**

*D. Feifarek, W.E. Hillwalker, A. Pastirik, SC Johnson / Global Safety Assessment & Regulatory Affairs; P. Mason, SC Johnson EurAFNE Limited / GSARA*

The European Food Safety Authority (EFSA) and European Chemicals Agency (ECHA), with support from the European Commission's Joint Research Centre (JRC), implemented guidance to identify endocrine disruptors in the context of biocidal products regulation (EU) No 528/2012 and plant protection products regulation (EC) No 1107/2009 in June, 2018. The guidance is entirely hazard-based and applies to active ingredients (*and* co-formulants in the case of biocides). It is, therefore, conceivable that chemicals may be pulled into the evaluation for which limited data are available. Three criteria are defined for classification of a chemical as an endocrine disruptor: adversity, endocrine activity, and a plausible link between the two. Here, we propose a system for evaluating the weight of evidence using existing data (e.g., adverse outcome pathways, in vitro mechanistic data) in the context of these criteria. The outcome is a ranking which may be utilized by the applicant to identify chemicals for which further evaluation is warranted.

**532 Life history traits and lipid profile changes after CP exposure**

*M. Castro, A. Sobek, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; M. Breitholtz, Inst för Tillämpad Miljövetenskap / Department of Applied Environmental Science (ITM); L. Asplund, Stockholm University / ACES; E. Gorokhova, Stockholm University / Department of Environmental Science and Analytical Chemistry (ACES)*

*Daphina magna* is a key freshwater species that, like many other animals, needs a balanced supply of nutrients to develop and reproduce successfully. However, not only food availability and quality but also exposure to certain environmental contaminants can affect the reproductive and developmental success of *Daphnia magna,* such as through the disruption of lipid homeostasis. Chlorinated paraffins constitute a group of complex industrial chemicals, divided into three categories based on their carbon chain length: short chain ($C_{10}$-$C_{13}$, SCCPs), medium chain ($C_{14}$-$C_{17}$, MCCPs) and long-chain ($C_{18}$-$C_{30}$, LCCPs). SCCPs have been added to the Persistent Organic Pollutants list by the Stockholm Convention, due to their persistence in the environment, bioaccumulation in wildlife and humans and toxicity towards aquatic organisms. Substitution of SCCPs by MCCPs and LCCPs is now underway. MCCPS and LCCPS are highly hydrophobic, with their log $K_{OW}$ ranging between 6 and 12, making their (necessary) aquatic toxicity assessment very complicated. Metabolomics approaches have shown that SCCPs are capable of disrupting the glycerophospholipid metabolism, fatty acid metabolism and purine metabolism in zebrafish embryos. Glycolysis, amino-acid metabolism β-oxidation disruption after SCCP exposure has also been described in HepG2 cells. To test the possible disruption of lipid homeostasis caused by CP-exposure in *D. magna*, we performed experiments following an adapted OECD guideline 211 (*Daphnia magna* reproduction test): first, through a stable exposure of our target chemicals through a passive dosing polymer, instead of a solvent carrier. Secondly, through the changing of the recommended algae-based diet established by the guideline (traditionally *Pseudokirchneriella subcapitata*) into a combined diet of *Eustigmatos magnus* and *Crytomonas sp. (*considered high quality food), in order to maximize the reproductive investment of the *D. magna* individuals. Neonates were exposed to two different CP technical mixtures (1 SCCP and another CP mixture covering all categories) at two different concentrations (50 and 100 μg/L), for 14 days. During this experiment, we recorded varied life history traits. After the experiment, the animals were collected for fatty acid profile analysis. This will allow us a better identification of the negative effects of chemical exposure on the reproductive output and lipid profile and, ultimately, aid the environmental hazard assessment of MCCPs.

## Modeling Oil and Chemical Transport in the Water Column After Spills

**533 Modeling oil in the water column after spills: An introduction to end-user needs and considerations for response and damage assessment applications**

*S.E. Allan, NOAA / Office of Response and Restoration*

After an oil spill, natural resource damage assessment efforts may rely on measured or modeled chemical concentrations in the water column to estimate exposure and injury to aquatic organisms. This data may also be important for emergency response, pre-spill planning, and risk assessments. Large-scale sampling programs that characterize three-dimensional chemical gradients over space and time may be logistically or financially infeasible. Models based on chemical and environmental parameters can fill gaps in field-collected data or allow spill observations to be translated into estimates of oil in the water column. A wide range of modeling tools are available for predicting oil concentrations in water under surface slicks and sheens. These models vary in their scale, resolution, data needs, outputs, and uncertainty. Understanding the range of tools that are available and their intended applications and limitations is critical for end-users. An introduction to needs and considerations for modeling oil concentrations in the shallow mixed layer of the water column will be presented in the context of their application to exposure and injury assessment and integration with other field-collected data and models. Examples from past spills will be presented and evaluated. This will provide context for an in-depth review and comparison of a range of newly developed and current use models.

**534 Water Column Exposure Modeling Tool**

*J.S. Bonner, Research, Applied Technology, Education, and Service, Inc.*

Considering the need for viable assessment modeling tools and the limited availability of empirical petroleum chemistry data from oil spills, we have developed a set of "simplified" modeling tools to estimate water column exposures of Total Petroleum Hydrocarbon (TPH) and 50 Polycyclic Aromatic Hydrocarbon compounds (PAH50) resulting from the entrainment, dissolution of surface oil into the upper water column and subsequent transport/and or ultimate fate of the relevant oil fractions. Oil from a surface slick is dispersed (or entrained) into the upper water column as a result of waves breaking on water surface areas covered with oil. The amount of oil entrained and dispersed is dependent on the oil thickness and viscosity, as well as sea state. The oil is injected to depths that scale with the wave height that is present during the entrainment period. Once oil is entrained at the surface, it is transported vertically through advection (stokes settling) and dispersion through the water column. Oil droplets in the near surface water column will rise back to the sea surface at rates dependent on their size and the oil buoyancy (i.e., Stoke's rise velocity). If turbulent mixing levels are sufficiently high, the oil droplets may remain in the water column, however, some portion of the oil entrained will rise to the sea surface during a model time step, with the cutoff droplet size (sizes larger than this value returned to the sea surface) dependent on the competing buoyant rise rate (allowing oil to resurface) and turbulent dispersion (causing the oil to remain dispersed subsurface). We have developed modeling tools to estimate surface oil entrainment/droplet formation/dissolution and upper water column concentrations of relevant petroleum hydrocarbons and attempted a simplified "inverse problem" to bracket the expected water column impact of these processes. We have also developed two additional tools to determine vertical distribution of fish eggs in the water column. These tools can be used together to determine petroleum hydrocarbons exposure of fish eggs in the water column. The vertical transport models for crude oil and/or fish eggs are based on the fundamental advection-diffusion equation.

**535 Modeling Near Surface Concentrations with a Lagrangian Element Oil Spill Model**

*C. Barker, NOAA Emergency Response; A. MacFadyen, NOAA*

The General NOAA Operational Modeling Environment (GNOME) is a particle tracking model developed and used by NOAA's Emergency Response Division for modeling oil spill fate and transport. GNOME was primarily designed to be used in emergency response and thus is very flexible in its use of inputs of the driving fields: winds, currents, and other parameters. Modeling in support of emergency response can be highly variable in scale and purpose: from predicting fate and transport for a small diesel spill to examining movement across the North Pacific of marine debris generated from the Japan tsunami. To support these broad use cases, GNOME has a model framework that allows multiple algorithms to be "plugged in" for different use cases, including behaviour of oils and other substances, 2 or 3 dimensional modeling, and various mixing algorithms, making it an excellent platform for exploring modeling approaches   Modeling the fate, transport, and dilution of petroleum products in the near surface presents a number of challenges. These include the fact that oil has many components with different solubilities, and thus forms surface slicks, droplets in the water column, and dissolved compounds, each of which are transported differently. In addition, the dynamics of the ocean surface are extremely complex, with effects from wind, waves, salinity gradients, heating and cooling, and other sub-mesoscale processes. Many of these processes are parameterized in oil spill models and hence may represent a significant source of variability among simulations.   Most oil spill fate and transport models use a Lagrangian element (particle tracking) approach. This paper will review the challenges of modeling oil concentrations in the near surface in general, and specifically the challenges of using a Lagrangian element approach. We will discuss multiple approaches for mixed layer modeling, and outline the methods used in the NOAA GNOME model. Examples from GNOME results will be used to illustrate the strengths and weaknesses of the approaches considered.

**536 Modeling Water Column Exposure Dynamics from Oil Spills: Issues, Model Approach and Validation**

*D.P. French-McCay, RPS Ocean Science*

For aquatic biota, quantification of oil and chemical exposure and effects is complicated by the high degree of spatial and temporal variability of in-water concentrations, as well as the organisms' distributions, movements, and sensitivity. Exposures to water column contamination above thresholds of concern are on the time scale of hours and spatial scales of meters. Further, oil is a mixture of thousands of hydrocarbons with varying physical-chemical properties and toxicity. As oil weathers in the environment, i.e., as evaporation, dissolution and (microbial and photo-) degradation ensue, the hydrocarbon composition in both the dissolved and particulate phases changes, as do the bulk properties of the oil, which affects fate and aquatic exposure. The SIMAP (Spill Impact Model Application Package) oil fate, exposure and effects model system has been developed over several decades to quantify oil and chemical exposures for support of risk assessments, emergency response decision-making, and natural resource damage assessment. The oil and chemical fate model tracks the movement of chemicals from oils and other mixtures using a Lagrangian approach, in which sublots and chemical components of the released pollutant mass are followed in space and time as they are transported, dispersed, and physically or chemically changed (i.e., entrainment, droplet/particulate formation, dissolution, volatilization, degradation, adsorption, etc.), accessing pathways of stressors and their concentrations at any desired/needed scale of spatial and temporal resolution. An integrated Lagrangian activity-based exposure model tracks the exposure history of individual biota to the mixture of chemicals through the affected environment using behavioral information and accounting for physical transport of plankton by currents. The response to the integrated exposure is evaluated with a pharmacokinetic-based toxicity model, accounting for the relative composition of the chemical mixture, as well as the influence of temperature and duration of exposure on the dose-response relationship. Example applications of this integrated model system for water column exposures after oil spills show their ephemeral nature, even for long-duration releases from a fixed source. Water column exposures estimated by SIMAP have been validated with field sample data from the North Cape and Deepwater Horizon oil spills.

**537 How mixed layer dynamics influences the evolution and exposure concentrations during an oil spill**

*C. Beegle, J. Skancke, T. Nordam, SINTEF Ocean / Environmental Technology*

The mixed layer is a dynamic feature of the ocean, which varies greatly by location and season. Even within the course of a day, the stratification in the upper water column can change with the differences in daytime solar heating and nighttime atmospheric cooling. Using the peer reviewed publications and available climatologies, we selected a variety of mixed layer profiles to explore the variety of conditions in the upper ocean around the world. Simple numerical oil droplet experiments, where droplets are released and allowed to rise in a given turbulence profile. We sample a variety of turbulence profiles so that we examine different mixed layer scenarios in order to show how these dynamics influence the amount and timing of oil surfacing. For example, as the mixed layer stratifies with either solar heating or freshwater input, vertical turbulence near the surface decreases, meaning that submerged droplets can have a higher probability of rising to the surface. These sample cases are designed to help provide intuition. More sophisticated cases are run in a fully 3D oil spill trajectory model. Using ocean circulation model output from various world regions and with different timing through the year, the variation is shown in how surface oil evolves under different conditions and in different areas. By using the 3D time dependent model, different oils, mixed layers and resulting exposures scenarios can be examined. Scenarios include a tropical, mid-latitude and Arctic case. A riverine case with freshwater over saline water is also examined. These 3D cases are run using the Oil Spill Contingency and Response (OSCAR) model, a highly peer reviewed oil spill trajectory, fate and effects model.

**538 Making sense of oil spill model results for the near surface water column: Extended capabilities of the Chemical/Oil Spill Impacts Model (COSIM)**

*S.M. Bartell, Cardno Entrix; J. Kubitz, Cardno; Y.B. Atalay, Cardno Entrix; J. Webber, J. Wakefield, Cardno; M.J. Fichera, ERM, Inc.*

Characterizing the ecological impacts of oil spills is a primary motivation for advancing capabilities in modeling oil spill transport and fate in the near surface water column. Increased accuracy in simulating spatial-temporal concentrations of oil chemical constituents are of minimal interest in absence of parallel developments in capabilities to transform these concentrations to estimated ecological effects. The Chemical/Oil Spill Impacts Model (COSIM) has advanced current oil spill risk assessment capabilities by including state-of-the-science algorithms to compute lethal and sublethal effects of oil constituents (hydrocarbon blocks) on organisms that inhabit the upper (~30 m) water column. An established target lipid model, empirical acute:chronic ratios, and an advanced phototoxicity algorithm combine to transform spatial-temporal concentrations of hydrocarbons (measured or modeled) to corresponding estimates of mortality and reduced growth for zooplankton, ichthyoplankton, and life stages of finfish defined by species life history and demography. A bioenergetics-based food web/ecosystem model appended to the core COSIM provides the capability to project the near-term (days) and longer-term (decadal) indirect ecological consequences of estimated direct lethal and sublethal population-level effects of oil exposure. The overall COSIM methodology addresses the highly variable distribution of biological productivity and marine resources in the upper water column and sensitive life history attributes (e.g., reproductive behavior) in assessing ecological risks and damages to resources. Basic life history information and population demographic data have been developed for more than 100 species commonly encountered in nearshore and offshore marine environments. This foundational database underpins the ability of the COSIM to assess the ecological impacts of oil spills. The COSIM will be presented as one methodology for adding assessment value to advances in oil spill fate and transport modeling in the near surface water column.

**539 Development of a Compound Particle Model for the Microbial Degradation of Oil Microdroplets Moving through a Water Column**

*G. Kapellos, Massachusetts Institute of Technology / Chemical Engineering; N. Kalogerakis, Technical University of Crete / Environmental Engineering; P.S. Doyle, Massachusetts Institute of Technology / Chemical Engineering*

After an oil spill in the sea, droplet clouds may be created either at the sea surface during the breakup of an oil slick by waves, or at the seafloor during the atomization of live crude oil extruding from a natural crack or a broken wellhead. Drifting droplet clouds pose a high risk of toxic effects to many marine species and, therefore, it is imperative to quantify the factors that determine their retention in the seawater column. We have recently developed a compound particle model for the biodegradation of solitary oil microdroplets moving through a water column (Kapellos et al., 2018). The compound particle is of the core-shell type and consists of an oily core that is successively surrounded by a bioreactive skin of negligible thickness and another bioreactive shell of finite thickness. The thin bioreactive skin represents a layer of superhydrophobic microbes that uptake oil directly from the oily phase, whereas the bioreactive shell represents a distinct biofilm phase. The new model accounts for all three modes of biodegradation: interfacial uptake, bioreaction in the bulk aqueous phase, and bioreaction in a biofilm formed around the droplet. Equations have been established for the determination of the droplet shrinking rate and the evolution of the compound particle dimensions as functions of the drifting speed, the microbial kinetics, the biofilm thickness, the diffusivity and solubility ratios. Numerical analysis is currently used to extend the domain of validity of the model by taking into account the effects of multiple oil components, oxygen limitation and biofilm erosion. Major findings of the theoretical analysis for the droplet retention in the water column will be discussed in conjunction with preliminary results from the biodegradation of hexadecane droplets by *Marinobacter sp.* in a microfluidic setting. Acknowledgements: This work has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 741799 (project "OILY MICROCOSM").

**540 Polar hydrocarbon compounds within surface water column following an oil spill**

*Y.B. Atalay, Cardno Entrix; J. Kubitz, Cardno*

Polarity is determined by how electrons within the atoms of a compound are arranged. In polar compounds, electrons are not uniformly distributed across the compound's structure and make certain parts of the compound more positively or negatively charged. Polarity underlies a number of physical properties including surface tension, solubility, and melting and boiling points. Some polar hydrocarbon compounds that contain nitrogen, sulphur and oxygen occur naturally in crude oils and refined petroleum products. In addition, weathering processes such as biodegradation and photo-oxidation have been shown to transform polycyclic aromatic hydrocarbons (PAHs) to oxygenated hydrocarbons (OxPAHs). In this paper, we will present a review of recent findings for polar hydrocarbon compounds and discuss how their environmental transport, fate and toxicity compare with nonpolar compounds, with specific emphasis on the near surface water column.

## Bivalves as Indicators of Exposure and Ecosystem Health

**541 Cellular Biomarker Responses of Freshwater Bivalves to Chlorpyrifos**

*T. Phan, T.D. Thomason, UNC Charlotte / Department of Biological Sciences; E. Johnson, NOAA / NCCOS / CCMA / National Centers for Coastal Ocean Science; A.P. Jacob, CSS / National Centers for Coastal Ocean Science; K. Kimbrough, National Oceanic and Atmospheric Administration; A.H. Ringwood, UNC Charlotte / Department of Biology*

Chlorpyrifos is the number one active ingredient used in many insecticides in the United States. The insecticide is mainly used for corn, soybean, and alfalfa agriculture, which are the top production crops in the US Midwest Region. The runoff from agriculture leads to very high concentrations of chlorpyrifos throughout the river basins of the Great Lakes, especially along the Maumee River basin. Environment concentrations of the insecticide often depend on proximity to the source, weather and when the insecticide was spray. Chlorpyrifos can have negative effects on freshwater ecosystems and organisms. Bivalves are valuable bioindicator organisms that can be used to characterize ecosystem health and monitor the effectiveness of remediation programs. However, many North American freshwater bivalves are threatened or endangered so studies with abundant invasive freshwater species such as *Corbicula fluminea* and *Dreissena polymorpha* were used to assess chlorpyrifos toxicity. One part of these investigations was in situ caging studies of *C. fluminea* and *D. polymorpha* conducted by the National Oceanic and Atmospheric Administration (NOAA) as part of the Mussel Watch program in the Maumee River Basin in Lake Eerie, in collaboration with the

Environmental Protection Agency (EPA). Cellular biomarkers (including acetylcholinesterase, lipid peroxidation and glutathione) of sublethal toxicity of clams and mussels from these field studies. Laboratory exposures of *C. fluminea* to environmentally relevant concentrations of 99% pure chlorpyrifos and commercially available Lorsban® were conducted at UNCC. Adverse effects in both bivalve species related to pesticide exposures, especially acetylcholinesterase, were observed. These studies will facilitate insights regarding the impacts and extent of chlorpyrifos on environmental health of freshwater ecosystems.

**542 Impact of environmental contaminants on aquatic life: Measurement of biomarkers of oxidatively induced DNA damage in dreissenid mussels by GC-MS/MS**

*P. Jaruga, E. Coskun, National Institute of Standards and Technology / Biomolecular Measurement Division; K. Kimbrough, National Oceanic and Atmospheric Administration; A.P. Jacob, CSS / National Centers for Coastal Ocean Science; E. Johnson, NOAA / NCCOS / CCMA / National Centers for Coastal Ocean Science; M. Dizdaroglu, National Institute of Standards and Technology / Biomolecular Measurement Division*

Using gas chromatography-tandem mass spectrometry (GC-MS/MS) with isotope dilution, we identified and quantified in the DNA isolated from dreissenid mussels numerous oxidatively-modified DNA bases and 8,5´-cyclopurine-2´-deoxynucleosides. We found significantly higher concentrations of these potentially mutagenic and/or lethal lesions in the DNA of mussels from the polluted locations as compared to the animals collected at the reference site in the Great Lakes. These results align with the National Oceanic and Atmospheric Administration's (NOAA) data showing that elevated concentrations of toxic compounds such as polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), trace metals or miscellaneous substances were found in mussels within the polluted area as compared to mussels collected in the reference site. The measured DNA lesions can be used as biomarkers for identifying DNA damage in mussels from polluted and reference sites. Such biomarkers are needed to identify the bioeffects of contaminants in affected organisms, as well as to determine whether remedial actions have proven successful in reducing observed toxic effects. The NOAA, National Center for Coastal Ocean Science, Mussel Watch Program (MWP), uses dreissenid mussels to monitor chemical contamination in the Great Lakes. Some of the contaminants, such as pharmaceuticals, may cause oxidatively induced DNA damage at low/unmeasurable concentrations. Therefore, we may detect and quantitate DNA damage without being able to measure the contaminant if it does not bioaccumulate, making DNA damage important even if we cannot link it to measured contaminants. DNA damage would signal a need for forensic chemistry in other matrices (POCIS – Polar Organic Chemical Integrative Samplers or SPMD – Semipermeable Membrane Devices) that accumulate contaminants that do not bioaccumulate in mussels. In recognizing the need for both chemical and biological monitoring information, the NOAA's MWP partnered with the National Institute of Standards and Technology (NIST), to conduct a pilot project to implement alternative biomonitoring techniques that complement chemicals concentrations measurements in mussels.

**543 Monitoring Exposure and Impacts of Toxics in The Great Lakes Area of Concern Using Genomic Biomarkers of Dreissena polymorpha**

*R. Klaper, N. Neureuther, University of Wisconsin-Milwaukee / School of Freshwater Sciences*

Great Lakes Areas of Concern are contaminated with both legacy contaminants and emerging contaminants which may be the cause of environmental degredation. Determining the potential for biological exposure over time can be difficult. In addition, it is difficult to identify the compounds that may be the greatest cause of biological degredation can be difficult in a mixture of hundreds of compounds that may be present. This project assessed the relationship of chemical exposure to the expression of key molecular biomarkers indicative of stress to 1) determine their potential to predict exposure to specific chemicals in situ 2) establish the impact of exposure length on biomarker reliability 3) aid in the evaluating the health of the Niagara River compared to its tributaries. In addition global gene expression analysis was used to determine how entire pathways may be altered in relation to particular exposures. Caged zebra mussels were placed in seven tributaries of the Niagara River in conjunction with NOAA's NCCOS Mussel Watch Program. Mussels were collected at five and ten weeks to determine exposure to contaminants in AOCs including PCBs, PAHs and contaminants of emerging concern. Additional mussels were collected to evaluate the relationship of chemical exposures to mRNA biomarkers critical to detoxification, including P-gP, GST, AHR and HSP70. Contamination in the Niagara River was found to be less than in its tributaries. At five weeks of exposure in contaminated sites all the genes were down regulated from control. AHR and GST significantly correlated with PCBs and PAHs, and the CECs 4 nonylphenol and triclocarban over a gradient of contamination, suggesting that these biomarkers have potential for environmental monitoring. Mussels exposed for ten weeks were not correlated to chemical measurements, indicating that time influences the efficacy of these biomarkers. As triclocarban in particular seemed to be associated most strongly with gene expression patterns a second experiment evaluating the impacts of TCC on gene expression was conducted. Gene expression of AHR, GST and P-gP biomarkers indicates that field data is supported by single chemical exposure data and that TCC may be having a significant environment impact in these estuaries.

**544 Considerations for Metabolomic Evaluation of Dreissenid Mussels as an Indicator of Aquatic Environments in the Great Lakes**

*T. Schock, NIST / Analytical Chemistry Division; E. Legrand, F. Casu, M. Watanabe, K. Hagiwara, National Institute of Standards and Technology; D.W. Bearden, National Institute of Standards and Technology / Chemical Sciences Division; E. Davenport, NOAA; K. Kimbrough, National Oceanic and Atmospheric Administration; A.P. Jacob, CSS / National Centers for Coastal Ocean Science; E. Johnson, NOAA / NCCOS / CCMA / National Centers for Coastal Ocean Science*

Environmental metabolomics focuses on detecting system-wide biochemical changes in organisms in response to environmental exposure. As ubiquitous, sessile, filter-feeders responsive to chemical contaminants, bivalves have been used as bioindicators in ecotoxicology. In order to validate this tool for risk assessment and environmental monitoring, it is important to ensure that the bioindicator will be vulnerable to exposure levels in the natural habitat; especially in ecosystems where chronic exposure levels may be low and physiological responses may be difficult to detect even with sensitive methods like metabolomics. In collaboration with the NOAA Mussel Watch Program, we evaluated dreissenid mussel metabolomes to assess aquatic environments in the Great Lakes. Whole-body polar extracts were characterized using nuclear magnetic resonance (NMR) spectroscopy and classified using multivariate statistics. We will present findings from two pilot studies at Milwaukee Estuary in Lake Michigan and Maumee River in Lake Erie. Specifically, we will discuss the challenges of validating an organism as an environmental indicator of exposure using a sensitive metabolomics approach. Spatial and temporal considerations, as well as handling effects on deployed organisms will be addressed. Additionally, metabolomic measurement methods for new matrices will be discussed in the context of technical reproducibility (sample preparation and instrumentation (specifically NMR)) and sample stability. Before experimental metabolic signatures of exposure can be compared, we must first understand the basic biology of the indicator organism at the location of interest and realize the variability and influence of biotic and abiotic factors. Acknowledging and comprehending these baseline data provides context for interpreting metabolic responses of exposure.

**545 Occurrence and spatial distribution of contaminants of emerging concern in Chesapeake Bay water, sediment, and oysters**

*K. He, University of Maryland Baltimore County / Chemical, Biochemical & Environmental Engineering; E. Hain, A. Feerick, University of Maryland, Baltimore County / Department of Chemical Biochemical and Environmental Engineering; A. Timm, USDA Forest Service; M. Tarnowski, Maryland Department of Natural Resources; L. Blaney, University of Maryland Baltimore County / Department of Chemical Biochemical and Environmental Engineering*

The Chesapeake Bay is the nation's largest estuary, but few studies have evaluated the occurrence and distribution of contaminants of emerging concern (CECs) in this important body of water. The potential input of CECs from urban and agricultural sources has not been spatially evaluated. Furthermore, the accumulation of CECs into critical species, such as the Eastern oyster (*Crassostrea virginica*), has not been assessed. These knowledge gaps were addressed by monitoring a suite of 43 antibiotics, 11 hormones, 13 ultraviolet-filters (UV-filters), and a wastewater loading indicator (*i.e.*, sucralose) in water, sediment, and oysters from more than 50 sites in the Chesapeake Bay. Water samples were extracted using hydrophilic-lipophilic balanced solid-phase extraction (SPE) cartridges. Sediment and tissue samples were freeze-dried, extracted by modified-QuEChERS, and cleaned by reverse-SPE. All analytes were measured using liquid chromatography with tandem mass spectrometry. Results showed the ubiquitous presence of CECs in the Chesapeake Bay. For example, the norfloxacin (94.1 ng/L), enrofloxacin (17.8 ng/L), sulfamethoxazole (14.8 ng/L), and clarithromycin (9.7 ng/L) antibiotics were detected in the water phase. Estrone and four UV-filters, namely ethylhexylmethoxycinnamate, homosalate, octocrylene, and oxybenzone, were frequently detected in Chesapeake Bay water, sediment, and oyster tissue. High concentrations of estrone (58.4 ng/g) and 17β-estradiol (11.5 ng/g) were measured in sediment at the mouth of the Manokin River. Homosalate was present at concentrations as high as 187.9 ng/L in water, 74.2 ng/g in sediment, and 158.3 ng/g in oyster tissue. Sucralose was used to track the source of CECs in Bay areas. Spatial differences were contextualized using available land use data overlaid with the locations of wastewater treatment plants and animal feeding operations. These results demonstrate the ubiquitous presence of CECs in the largest estuary of the United States, and provide important motivation for studying the potentially deleterious effects of antibiotic resistance and endocrine disruption in the Chesapeake Bay.

**546 The environmental monitoring of operational discharges of oil and gas activity in the North Sea using caged mussels**

*D.M. Pampanin, International Research Institute of Stavanger / University of Stavanger / Environment; S.J. Brooks, Norwegian Institute for Water Research NIVA; S. Sanni, IRIS / UiS / Environment; E. Lyng, International Research Institute of Stavanger / Environment; B.E. Grøsvik, Institute of Marine Research*

Oil and gas companies operating on the Norwegian Continental Shelf are required to carry out environmental monitoring to obtain information on the actual environmental impacts of their activities and to give authorities a better basis for regulation. Scientists, operators and regulators have worked cooperatively for two decades in this program, for implementing knowledge, developing methods and tools to manage the offshore produced water (PW) discharges. A multidisciplinary approach (e.g. chemistry, biology, modelling and risk assessment) is in use at present to monitor discharges and reduce risks. In 2015, the Norwegian Environmental Agency published new guidelines as a result of the research activity performed since 1995. The new requirements have been applied for the first time in 2017. The holistic approach shows a significant improvement in the scientific outcomes of the monitoring, in a cost-effective way. The regulation includes mandatory monitoring using caged mussels and the use of biomarkers as early warning signals of potential adverse effects. A total of 19 stations were chosen: 17 around the PW discharged point, and 2 reference stations. The study design was based on the updated regional dose-related risk and effects management model (DREAM). At each station mussels were placed in mesh bags at a depth of 18 m. Mussels were collected after 6 weeks field exposure and the following parameters analysed: gene expression in gill, acetylcholinesterase, micronucleus assay, lysosomal membrane stability, histological evaluation of gills and gonads, survival in air and condition index. In addition, PAH and metal content were analysed as body burden. Summarising some of the results, the environmental monitoring study design was successful, with caged mussels exposed to the PW gradient following the forecasted plume. Higher level biomarkers, such as survival in air and condition index, did not show significant differences between mussels from the various stations. Lower level biomarkers (cellular), indicated a potential genotoxic effect of the PW discharge in organisms caged up to 100 m form the discharge point. The studied PW discharge point is in a highly active zone, where more platforms are present, the contribution of these platforms need to be considered.

**547 Measuring Cellular Energy Allocation in common bivalve species using Near Infra-red Spectroscopy**

*W.A. Maher, J. Bartlett, University of Canberra / Institute for Applied Ecology; M. Purss, University of Canberra*

The function and sustainability of organisms, populations and ecosystems are driven by the input, use and transfer of energy. The storage and transfer of energy in organisms is influenced by environmental stress from physiochemical changes and contamination. Cellular Energy Allocation (CEA) is a measure of energy stores (protein, lipids and glycogen) versus energy consumption (ETS) and provides a measure of organism response to stress both natural and anthropogenic. The capacity to rapidly assess CEA would provide a valuable tool to assess organisms' responses to both physiochemical stressors such as temperature, salinity, pH and oxygen changes and anthropogenic influences. This study present an approach for rapid CEA measurements in five bivalve species (*Saccostrea glomerata* (Sydney Rock Oyster), *Ostrea angasi* (Flat Oyster), *Mytilus galloprovincialis* (Australian Blue Mussel), *Crassostra gigas* (Pacific Oyster and *Anadara trapezia* (Sydney Cockles) using near infrared spectroscopy

**548 Glutathione – Linkages Between Antioxidant Capacity and Sensitivity**

*A.H. Ringwood, UNC-Charlotte / Department of Biology; B. Khan, National Research Council of the National Academies / USEPA / Atlantic Ecology Division; M. Lowder, Discovery Place Science; T. Phan, T.D. Thomason, UNC Charlotte / Department of Biological Sciences; T.R. Gaspar, University of North Carolina at Charlotte / Biology; K. Edge, NSW Environment Protection Authority; E. Johnson, NOAA / CCMA / National Centers for Coastal Ocean Science; A.P. Jacob, CSS / National Centers for Coastal Ocean Science; K. Kimbrough, National Oceanic and Atmospheric Administration*

Glutathione (GSH) is one of the most abundant antioxidants and also serves critical roles in numerous other pathways related to detoxification and scavenging of free radicals. The GSH responses of a variety of bivalves, both marine and freshwater, from a variety of locations around the world (southeastern US, Australia, Great Lakes USA, etc.) are presented. As a biomarker, both increased levels and depletion indicate pollutant exposure and stress. Numerous studies, including the zebra mussel and oyster studies presented here have shown increased GSH levels that are correlated to tissue levels of PCBs and PAHs. In contrast, depleted GSH levels have been observed in response to metal exposures and other stressors. Glutathione depletion can be especially problematic as it reflects that overall antioxidant capacity is significantly compromised, leading to greater sensitivity to additional stressors and widespread tissue damage. Similarly species or life history stages that have low GSH levels would be expected to be more sensitive to pollutant stressors. Our studies have indicated that freshwater bivalves have much lower baseline GSH levels than marine bivalves; the GSH levels of zebra mussels and Asian clams are an order of magnitude lower (approximately 1/10) than oysters and mussels. We have previously shown that larvae from GSH depleted parents are much more susceptible to pollutants. Glutathione serves as

a valuable screening level biomarker tightly linked to total antioxidant capacity that can be reliably measured and that provides valuable insights regarding pollutant effects and species-specific sensitivities.

## Novel Approaches for Understanding Diversity in Species Sensitivity to Chemicals

**549 Addressing species diversity in biotransformation: Variability in expressed transcripts of hepatic biotransformation enzymes among fishes**

*K.A. Fay, General Dynamics Information Technology; J. Doering, NRC / USEPA / Mid-Continent Ecology Division; J. Swintek, Badger Technical Services; B. Auch, University of Minnesota Genomics Center; T. Kono, Minnesota Supercomputing Institute; D. Feifarek, USEPA; S. Poole, USEPA / National Health and Environmental Effects Research Laboratory; J.E. Cavallin, Badger Technical Services / National Health and Environmental Effects Research Laboratory; D.L. Villeneuve, G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory*

There is increasing evidence that diverse xenobiotic metabolizing enzymes exist among fishes, potentially resulting in different chemical sensitivities and accumulation, but this has never been systematically evaluated. One concern is that model test species such as rainbow trout, zebrafish and fathead minnows may not adequately represent the xenobiotic metabolizing capacity of other fish species. Our current study performed full-transcript, isoform sequencing on liver samples from two dozen phylogenetically diverse fish species. This novel RNAseq approach eliminated the need for transcriptome reconstruction resulting in reference genomes of the highest precision, allowing for detection of enzyme isoform orthologs among the species, as well as the nuclear receptors that control expression of the enzymes. Species were selected for broad phylogenetic coverage, as well as economic, research, and conservation importance, and included: sea lamprey (*Petromyzon marinus*), lake sturgeon (*Acipenser fluvenscens*), American eel *(Anguilla rostrate)*, alligator gar *(Atractosteus spatula)*, paddlefish *(Polyodon spathula)*, rainbow trout (*Oncorhynchus mykiss*), rainbow smelt *(Osmerus mordax)*, fathead minnow *(Pimephales promelas)*, Antarctic icefish (*Trematomus loennbergii*), common carp (*Cyprinus carpio*), and channel catfish (*Ictalurus punctatus*). Publicly available liver transcriptome data generated using the traditional Illumina RNAseq methods provided an additional 17 fish species, as well as mutual coverage for 5 fish species analyzed using the full-transcript read method. Together, the data suggest ostensibly important xenobiotic biotransforming enzymes, such as CYP1A orthologs are missing in some fish clades, while other enzyme families (e.g., CYP4V) are prevalently expressed across phylogenetically distinct fishes.

**550 Phylogenetic origins for differences in detoxification enzymes in fish and other vertebrates**

*P. van den Hurk, Clemson University / Biological Sciences*

Over the last decades, more and more examples have been discovered of perplexing differences in the expression of phase 2 detoxification enzymes in vertebrate species. These enzymes, also known as drug-metabolizing enzymes, comprise groups as the sulfotransferases, UDP-glucuronosyltransferases, and glutathione S-transferases. They are involved in conjugating a hydrophilic group to a poorly water soluble substrate, thus reducing the biological activity or toxicity of the substrate, and facilitating the excretion of the conjugated complex. To further investigate species differences in marine fish taxa, a variety of species was evaluated for the activity of sulfation and glucuronidation enzymes, using the natural hormone 17B-estradiol and the environmental toxicant 9-hydroxy-benzo[a]pyrene as substrates. Primitive fish species like hagfish and lamprey appeared to have no glucuronidation activity towards these substrates, while activity in sharks and rays was much lower than in bony fishes. This would indicate that the earliest vertebrates had no glucuronidation capacity, and that the array of glucuronosyltransferases that is known in more modern fish species and other vertebrates has evolved later. However, there are dramatic examples of other vertebrates that don't have glucuronidation capability towards phenolic substrates. We performed experiments to demonstrate that a number of snake species also lack phenol-type glucuronidation activity; while other reptilians like turtles and alligators had much lower activity than mammals. The lack of phenol-type glucuronidation enzymes, combined with the lack of N-acetyltransferase, leads to an accumulation of highly toxic aminophenol in snakes when exposed to acetaminophen, which phenomenon is used to control the invasive brown treesnake in Guam. In addition, even among the mammals it has been known that the felines lack phenol-type glucuronidation activity, which makes them extremely sensitive to compounds like acetaminophen. The explanation for this diverse expression of glucuronosyltransferases in different vertebrate taxa is probably a combination of phylogenetic origins and the degradation of genomic information in genes that are not essential, like phenol-type glucuronosyltransferases in obligate carnivores like cats, snakes and alligators.

**551 An non-targeted approach to evaluate endocrine disrupting activities of environmental contaminants in non-model species**

*S. Kohno, H.L. Schoenfuss, St. Cloud State University / Aquatic Toxicology Laboratory*

Contaminants of emerging concerns (CECs) have been detected ubiquitously in aquatic environments, and their biological effects are problematic in the molecular and reproductive investigations at both field and laboratory. Especially, it is important to evaluate their long-term effects such as non-lethal endocrine disrupting effects in special concern species. However, it is very difficult to conduct whole organism exposure experiments in the threatened or endangered species. Therefore, it is critical to develop non-invasive assays customized for each species to evaluate endocrine activities on nuclear hormone receptors in vitro. To obtain sequence information, Hepatic or hepatopancreatic transcriptome of the lake sturgeon (*Acipenser fulvescens*) and freshwater mussels (Plain Pocketbook, *Lampsilis cardium* and Higgins Eye Pearlymussel, *Lampsilis higginsii*) were analyzed using the PacBio Iso-Seq method, which produces full-length transcripts *de novo*. Iso-Seq analyses obtained approximately 5000 of high-quality consensus sequences of each species. And then, Cogent analyses reconstructed approximately 2000 of the coding genome sequences from the consensus transcriptomes of these species. Blast2Go followed by InterProScan functionally annotated and classified these sequences. Identified 15 sequences of A. fulvescens nuclear hormone receptors were orthologous with androgen receptor, estrogen receptor, vitamin D3 receptor, peroxisome proliferator-activated receptor (PPAR), hepatocyte nuclear factor, chicken ovalbumin upstream promoter-transcription factor (COUP-TF) and orphan receptors. Four sequences of nuclear hormone receptors were identified each in L. cardium and L. higginsii. L. cardium sequences were homologous with hepatocyte nuclear factor 4, COUP-TF1, retinoid X receptor (RXR) α and γ, while L. higginsii sequences were homologous with ecdysone-induced protein 75b, COUP-TF1, PPARγ and RXRα. These nuclear hormone receptors need to be analyzed to assess the endocrine disrupting effects of CECs in liver and hepatopancreas. To avoid a potential artifact of different sequence affinity in the hormone response element among species, endocrine activities of CECs would be evaluated by quantifying transcriptional activities using a chimera protein of the ligand-binding domain and a universal DNA-binding. These assays would noninvasively reveal a potential long-term effects of CECs even in special concern species.

**552 A generalized individual-based model to assess sublethal impacts of contaminants on larval fish cohort growth and survival**

*L. Ivan, J. Albers, Michigan State University / Fisheries and Wildlife; R. Klingler, J. Larson, University of Wisconsin Milwaukee / School of Freshwater Sciences; B.M. Armstrong, State of Michigan / Environmental Quality; B. Clark, Atlantic Ecology Division / USEPA / Environmental Effects Research Laboratory; D.E. Nacci, USEPA / Atlantic Ecology Division; M. Jones, Michigan State University / Department of Fisheries and Wildlife; N. Vinas, US Army / Engineer Research and Development Center; M.J. Carvan, University of Wisconsin-Milwaukee / School of Freshwater Sciences; C.A. Murphy, Michigan State University / Department of Fisheries and Wildlife*

There are thousands of contaminants and thousands of species to assess for contaminant exposure, making assessment of the impacts of these chemicals extremely complicated, expensive and time-consuming. Sublethal impacts of contaminants are often subtle and difficult to assess at higher levels of organization, and this is especially true for behavioral impacts. We developed a generalized individual-based model (IBM) that examines the sublethal effects of a contaminant, as measured through behavioral alterations, on a larval fish cohort growth and survival. On each simulated day, larvae forage for prey, grow, and are subject to starvation and predation mortality. Sublethal effects on behavior, as measured from laboratory studies, are incorporated into foraging via multipliers on larval swimming speed, capture success and handling time, and into predation mortality via the larval swimming speed multiplier. To understand which model parameters are most critical to model cohort survival and growth, we included a sensitivity analysis using a select suite of parameters that have previously shown to be sensitive in similar models. For this analysis, we explore the impacts of PCB126 and methylmercury (MeHg) on swimming speed in larval yellow perch (*Perca flavescens*). We tested the hypothesis that, while the sublethal impacts of contaminants on swimming speed are subtle, they can still have significant impacts on yellow perch cohort growth and survival. Further, we examined how well we could assess the sublethal impacts of these contaminants on larval perch in the face of model uncertainty. We hypothesized that the sublethal impacts on larval yellow perch swimming speed will be less than the uncertainty included in model. Future development of the model will include additional sublethal impacts on prey capture success and handling time. We will then expand this generalizable model to evaluate if model species like killifish (*Fundulus heteroclitus*) and fathead minnows (*Pimephales promelas*) respond in a similar manner as yellow perch to contaminants. This work will facilitate cross-species extrapolations and help determine risk to ecologically relevant populations.

**553 Cross-species Applicability of a Quantitative AOP Describing Inhibition of Aromatase Activity Leading to Reproductive Dysfunction in Fathead Minnow**

*J.A. Doering, USEPA / Mid-Continent Ecology Division; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; B.R. Blackwell, USEPA / ORD / National Health and Environmental Effects Research Laboratory; J.E. Cavallin, Badger Technical Services / National Health and Environmental Effects Research Laboratory; K. Dean, Oak Ridge Institute for Science Education at USEPA; K.A. Fay, General Dynamics Information Technology; D. Feifarek, SC Johnson / GSARA; K.M. Jensen, USEPA / Mid-Continent Ecology Division; M. Kahl, USEPA / National Health and Environmental Effects Research Laboratory; C. LaLone, USEPA / Mid-Continent Ecology Division; S. Poole, USEPA Mid-Continent Ecology Div / National Health and Environmental Effects Research Laboratory; E. Randolph, EPA / National Health and Environmental Effects Research Laboratory; C. Tilton, USEPA / ORD; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory*

Quantitative adverse outcome pathways (qAOPs) describe quantitative response-response relationships linking the molecular initiating event (MIE) and adverse outcome (AO). Such qAOPs enable quantitative prediction of the probability of occurrence or severity of an AO for a given magnitude of chemical interaction with an MIE. A qAOP has been developed for inhibition of cytochrome P450 aromatase (CYP19) leading to reproductive dysfunction through decreased circulating estradiol (E2) thereby reducing circulating vitellogenin (VTG). This qAOP was developed based on quantitative data from the fathead minnow (*Pimephales promelas*). However, different reproductive physiologies exist among fishes. Therefore, it was unknown whether a qAOP developed for fathead minnow would be predictive of reproductive dysfunction in other fishes. This study investigated whether this qAOP could accurately predict adverse responses to the model CYP19 inhibitor fadrozole, for three other fishes, namely Japanese medaka (*Oryzias latipes*), zebrafish (*Danio rerio*), and mosquitofish (*Gambusia affinis*). Japanese medaka and zebrafish have asynchronous oocyte development in common with fathead minnow, while mosquitofish have group-synchronous oocyte development. In vitro CYP19 inhibition assays demonstrate comparable sensitivities to fadrozole among fathead minnow, Japanese medaka, and zebrafish, while CYP19 of mosquitofish is 16-fold more sensitive. Results of 21-day reproductive assays demonstrate quantitatively comparable responses to fadrozole for E2, VTG, and egg production among the three asynchronous fishes. In contrast, fadrozole did not reduce E2 or VTG in mosquitofish and had limited effect on fecundity. Expression of CYP19 increased by up to 13-fold in the gonad of mosquitofish relative to up to 2-fold in fathead minnow. This suggests that mosquitofish, and potentially other group-synchronous fishes, have greater capacity to compensate for inhibition through up-regulation of CYP19. Overall, results of this study suggest that the qAOP developed for fathead minnow might be broadly applicable to fishes with asynchronous oocyte development, which includes numerous small-bodied fishes. But, the qAOP is unlikely to be applicable to fishes with group-synchronous oocyte development, such as catfish, trout, and sturgeons. This information could be essential in guiding more objective ecological risk assessments of fishes to aromatase inhibiting chemicals.

**554 Development of a neurobehavioral AOP for fish larva: Incorporating ecologically relevant behavioral alterations after exposure to PCB 126 and MeHg**

*J. Albers, Michigan State University / Fisheries and Wildlife; R. Klingler, University of Wisconsin, Milwaukee / School of Freshwater Sciences; L. Ivan, Michigan State University / Department of Fisheries and Wildlife; D.E. Nacci, USEPA / Atlantic Ecology Division; B. Clark, Atlantic Ecology Division / USEPA / Environmental Effects Research Laboratory; M. Jones, Michigan State University / Department of Fisheries and Wildlife; N. Garcia-Reyero, US Army Engineer Research and Development Center; M.J. Carvan, University of Wisconsin, Milwaukee / School of Freshwater Sciences; C. Murphy, Michigan State University / Department of Fisheries and Wildlife*

Behavior is often measured in ecotoxicology studies because it is a sensitive endpoint that can indicate impairments after chemical exposure. However, it is challenging to link subtle behavioral changes to population relevant metrics and it is difficult to obtain this information on ecologically relevant species. We used the Adverse Outcome Pathway (AOP) as a framework to design laboratory and simulation studies that will tackle these issues. We conducted behavioral assays on four fish species to determine how differing sublethal levels of PCB 126 and methylmercury (MeHg) change larval fish behavior. Both traditional reference fish species such as zebrafish (*Danio rerio)* and fathead minnow (*Pimephales promelas)* were tested, as well as those more relevant to conservation such as yellow perch (*Perca flavescens)* and killifish (*Fundulus heteroclitus).* Methods focused on standardizing data collection and analyses to make them applicable to all fish species. Using video analysis, we measured behaviors on individual fish that can be translated to simulated population level outcomes (such as cohort survival and growth), and these behaviors include average swimming speed, overall activity and feeding rate. Preliminary behavior analyses of yellow perch indicate a non-linear response to increased chemical concentration for both MeHg and PCB 126 in total distance traveled, swimming bout frequency and duration, and that such responses are comparable between species after standardization. After behavioral assay analyses are complete, we will compare between all species and the relative impacts of contaminants on behavior will be used to estimate population level effects using individual based models (IBMs). Our approach demonstrates how the AOP framework can be used to develop measureable key events for neurobehavioral effects after exposure to contaminants that could predict population outcomes of ecological relevant species.

**555 Can genomic copy number variants inform us about within-species toxicant susceptibility variation?**

*L.A. Holden, US Army Public Health Center / Toxicology; K.H. Brown, Portland State University / Biology*

Physiological variation induced by genomic copy number variants (CNV) have received tremendous attention in human disease research, but little work outside of this domain has been conducted. We used a model vertebrate system to establish the connection between genomic CNV and variation in toxicant susceptibility within a species. We assessed three zebrafish (*Danio rerio*) strains with variable toxicant susceptibility phenotypes using microarrays to identify CNV associated with PCB-126 induced gene expression differences (response eQTL) and confirmed our findings using targeted mutagenesis and a developmental toxicity assay. Using the 895 CNV found at high frequency within strains, the 124 differentially expressed mRNAs in females, and the 97 differentially expressed mRNAs in males (following 24 hours of 130 ng PCB-126/L), we identified two sex-specific response eQTL. The response eQTL in AB strain females modulates expression of *prpf4*, a gene associated with the splicosome and cellular stress, while the response eQTL in Tubingen (TU) strain males modulates expression of *dync2h1*, a gene associated with resistance to multiple compounds due to altered lipid partitioning. To test our hypothesis that CNV are drivers of PBC-susceptibility within species, we performed targeted mutagenesis using CRISPR-Cas9. Because the response eQTL in AB strain zebrafish appears to provide protection from the toxic effects of PCB-126 (AB are more resistant), we expected that CRISPR-mutant (crispant) AB zebrafish would show higher sensitivity to PCB-126. Conversely, the CNV in TU zebrafish associates with increased sensitivity, so we expected crispant TU to have higher resistance to PCB-126. Therefore we injected 1-cell stage embryos with CRISPR-Cas9 ribonucleic protein complexes targeted to the strain-specific response eQTL CNV, exposed embryos to 5-3125 ppb PCB-126 for 24 hours, and assessed developmental toxicity by heart rate, edema, and morphology until 5 days post fertilization. In support of our hypothesis, crispant AB zebrafish showed a reduction of $EC_{50}$ values by a factor of 10, from 627.7 to 67.9 ppb PCB-126, as compared to controls. Crispant TU zebrafish had slightly increased $EC_{50}$ values, from 35.3 to 47.0 ppb PCB-126, as compared to controls. This study shows clear evidence of CNV as drivers of the PCB-susceptibility variation within a species and is a first step towards inclusion of genomic CNV into modeling who or what will be susceptible to PCB exposure.

**556 Influence of life-history parameters on patterns of persistent organic pollutants in eastern North Pacific gray whales (*Eschrichtius robustus*)**

*K. Hayes, Texas Tech University / Environmental Toxicology; G.M. Ylitalo, NOAA Fisheries / Northwest Fisheries Science Center; T.A. Anderson, Texas Tech University / Environmental Toxicology; J. Urbán-Ramírez, Universidad Autónoma de Baja California Sur / Departamento de Biología Marina; J. Jacobsen, V.E. Enterprises / Department of Biological Sciences; D. Boyd, K.A. Baugh, J.L. Bolton, NOAA Fisheries / National Marine Fisheries Service / Northwest Fisheries Science Center; A. Lang, NOAA Fisheries / Southwest Fisheries Science Center; J. Scordino, Makah Fisheries Management, Makah Tribe / Makah Fisheries Management; S. Martínez-Aguilar, Universidad Autónoma de Baja California Sur / Departamento de Biología Marina; J.C. Calambokidis, Cascadia Research Collective; A. Brüniche-Olsen, Purdue University / Department of Forestry and Natural Resources; M.O. Gribble, Emory University / Environmental Health; C.A. Godard-Codding, Texas Tech University/ TIEHH / Department of Environmental Toxicology*

The presence of persistent organic pollutants (POPs) in the marine environment is of global concern and have been associated with developmental dysfunction, reproductive failure, and immunosuppression in marine mammals. Research conducted in the 1980s-1990s reported POPs in eastern North Pacific (ENP) gray whale (Eschrichtius robustus) blubber but contemporary data were lacking. The current study examined blubber contaminant trends across various life history parameters including sex, age, and reproductive status in ENP gray whales. Blubber biopsies (n=121) were collected from free-swimming whales between 2003 and 2017 along the pacific coast of CAN, USA and Baja, California, MEX. To investigate maternal offloading, 19 mother and calf pairs plus 13 unpaired calves and 4 mothers were sampled. POPs and lipids were extracted from gray whale blubber samples using dichloromethane with accelerated solvent extraction, a previously validated analytical methodology. Sample cleanup was conducted using silica/alumina column chromatography and size-exclusion high-performance liquid chromatography. POPs including dichlorodiphenyltrichloroethanes (DDTs), chlordanes (CHLDs), hexachlorocyclohexanes (HCHs), polychlorinated biphenyls (PCBs), and polybrominated diphenyl ethers (PBDEs) were determined in blubber extracts using gas chromatography/mass spectrometry. Blubber lipid content was determined gravimetrically. Mean POP blubber concentrations (wet weight) were $60 \pm 7$ ng/g ΣPCBs, $65 \pm 11$ ng/g ΣDDTs, $24 \pm 3$ ng/g ΣCHLDs, $18 \pm 2$ ng/g ΣHCHs, and $19 \pm 2$ ng/g ΣPBDEs. A subset of 96 samples and 18 analytes were used for statistical modeling and revealed significant life-history-related POP trends using linear regression of log-transformed congeners with multiple imputation and robust standard errors. Adult males had significantly higher POP concentrations than adult females, presumably due to maternal offloading. Young whales in this study had similar concentrations across sexes. Reproductively inactive adult females had slightly higher contaminant concentrations than females with calves. Mother and calf contaminant concentrations were similar although contaminant concentrations in calves were statistically higher. Our study provides current POP concentration data that enhances knowledge of POP trends across various life history stages in this protected species.

# Impacts of Unconventional Gas Operations on Surface Waters, Soils and Groundwater – An International Perspective

**557 Assessment of the likelihood of contaminant migration pathways in Australian coal seam gas basins**

*D. Mallants, CSIRO Land and Water; R. Jeffrey, Strata Control Technology; X. Zhang, B. Wu, J. Kear, Z. Chen, B. Wu, E. Bekele, M. Raiber, CSIRO; S. Apte, Centre for Environmental Contaminants Research; B. Gray, Department of the Environment and Energy*

Coal seam gas (CSG) or coal bed methane production has grown exponentially in Australia over the last two decades with currently nearly 7,000 productive wells and another 18,750 wells planned over the next five to ten years. Concerns over environmental contamination by hydraulic fracture fluids (HFF) stem from (i) incidents involving poor surface handling of HFF and other fluids with potential migration pathways in soil and shallow groundwater, and (ii) leakage pathways arising from HFF injection into coal seams and unintended migration of these chemicals. A review of international studies on unconventional gas migration pathway studies was undertaken to provide prior knowledge for use in an Australian study. Whilst many of the leakage pathways considered in North American shale gas basins involved either (i) pre-existing fractures and faults, or (ii) up the production well due to poor casing or cementing, additional potential pathways highlighted for Australian CSG basins are, (iii) connectivity between CSG wells and water bores via a fracture in or extended out of the coal seam formation, and (iv) due to poor integrity water bores. Previous studies from the US have shown that natural pathways of fluid leakage exist between some shale reservoirs and shallow groundwater based on hydrochemical and environmental tracer data. However, analysis of micro-seismic and groundwater hydrochemistry data, and geologic modelling of vertical fracture growth reveal a low risk of leakage pathways developing in shallow aquifers confined by deep shale formations. This is due to limitations on the fracture growth vertically across aquitards often hundreds of meters thick, retention within the shale of limited amounts of injected fluid, and preferential fracture growth at shallow depths in the horizontal direction. The review identifies geologic criteria based on modelling and observations which support reduced risk of leakage pathways developing during CSG production in Australian basins. These include encountering certain favourable conditions during drilling/injection, i.e. (i) interfaces, such as natural fractures, faults, and bedding planes, which promote offsetting and branching, or rock layers with higher fracture toughness causing the cessation or reduction in fracture growth, (ii) narrow fractures due to a relatively higher elastic modulus, leading to higher viscous flow loss, (iii) high permeability layers, and (iv) overlying layer(s) with a higher confining stress.

**558 Release of geogenic contaminants during coal bed methane extraction: Laboratory studies**

*S. Apte, Centre for Environmental Contaminants Research; R.S. Kookana, M. Williams, CSIRO Land and Water; G.E. Batley, CSIRO Land and Water / Centre for Environmental Contaminants Research; C.V. Jarolimek, J. King, CSIRO Land and Water*

Concerns surrounding the use of hydraulic fracturing as part of the coal bed methane extraction process have mainly centred on the potential human health and environmental effects of the chemicals that are the constituents of hydraulic fracturing fluids. However, as part of their natural mineral composition, coal seams contain a number of geogenic contaminants that have the potential to be mobilised by the processes used to extract gas. These geogenic contaminants can be released from coal seams through the effects of chemicals such as chelating agents, acids, surfactants and solvents that are used in hydraulic fracturing. A laboratory-based study was conducted that investigated the potential for release of geogenic contaminants (inorganic and organic) from coal samples taken from locations across eastern Australia. Synthetic hydraulic fracturing fluid were prepared and used to leach coal samples under conditions representative of field conditions. The laboratory tests were designed to provide worst case estimates of the release of geogenic contaminants in the presence and absence of hydraulic fracturing chemicals. The logic for this approach was that if a contaminant was not detected during these laboratory simulations conducted under deliberately harsh conditions, then it was unlikely to be detected in samples obtained from an actual gas extraction operation. Detectable concentrations of over 42 trace elements were observed in the leach tests conducted. Based on comparisons with available surface water quality guideline values for aquatic ecosystem protection, the following inorganic geogenic contaminants were priorities for further investigations: Al, B, Cr, Co, Cu, Hg, Mn, Se, Tl, U and V. Phenol and cresols were the most commonly detected organic compounds particularly in the presence of the synthetic mixture of hydraulic fracturing chemicals. Higher concentrations of phenols and other low molecular weight total recoverable hydrocarbons in the $C_{10}$-$C_{14}$ range were released on leaching of coal samples with synthetic groundwater mixed with hydraulic fracturing chemicals compared to leaching with synthetic groundwater alone.

**559 Nontarget analysis of produced waters from two wells of different age in the Eagle Ford Shale Play, Texas, USA**

*J. Bobbitt, Baylor University / Chemistry and Biochemistry; G.N. Saari, Baylor University / Department of Environmental Science; K. Chambliss, Baylor University / Department of Chemistry and Biochemistry; N.D. Denslow, University of Florida / Physiological Sciences; B.W. Brooks, Baylor University / Department of Environmental Science*

Hydraulic fracturing is a major method for natural resource extraction that has become popular in recent years. The process works by pumping aqueous fluids into shales that are gas- and oil-rich. Fracking fluid is mostly made up of water and sand with the remaining fraction (less than 1%) containing chemicals such as surfactants, clay stabilizers and biocides. Flowback and produced waters (i.e. fracking fluid mixed with native released groundwater contain heavy metals and a variety of organic compounds) can potentially mix with nearby aquifers and/or surface water. Due to the lack of knowledge on aquatic contamination from this process, particularly for well of different ages of operation, a more advanced understanding of diverse constituents is needed. However, the proprietary nature and complex composition makes the analysis of fracking fluid even more challenging. A variety of analysis techniques will be needed to monitor the wide range of chemical constituents. Nontarget liquid chromatography high resolution mass spectrometry (LC-HRMS) is an emerging technique for analyzing complex chemical mixtures and has recently been used in various environmental studies. In our study, fracking flowback and produced water from two different wells from the Eagle Ford Shale play south of San Antonio, Texas, USA were selected for study. These wells varied in age by 2.5 years (well A had been in operation for 36 months, and well B in operation for 6 months). We employed standard toxicity identification evaluation procedures to fractionate samples from both wells and then analyzed these fractions using a nontarget LC-HRMS method. Preliminary results show that the methanol fraction contained a relatively large abundance of polyethylene glycol (PEG) species in both wells. A more in-depth analysis of the chromatograms showed that well A consisted of PEG species with longer retention times, while well B primarily consisted of PEG species with shorter retention times. Furthermore, Kendrick mass analysis (i.e. identification of homologous series) showed that well A and B consisted of 6 and 5 different PEG species, respectively. Thus far, the results from the nontarget LC-HRMS method have only identified PEG species. Nonetheless, the observed differences in the PEG species demonstrates that a nontarget LC-HRMS and Kendrick mass analysis method will be useful for providing PEG chemical fingerprint identifiers for fracking fluid and/or flowback and produced well water samples.

### 560 Chemical and bioassay assessment of waters related to hydraulic fracturing at a tight gas production site

*A. Faber, Copernicus Institute Utrecht University / Environmental Sciences; M. Annevelink, KWR Watercycle Research Institute; P. Schot, Copernicus Institute Utrecht University / Environmental Sciences; K. Baken, KWR Watercycle Research Institute / CWG; M. Schriks, E. Emke, KWR Watercycle Research Institute; P. de Voogt, University of Amsterdam / IBED; A. van Wezel, KWR Watercycle Research Institute / Chemical Water Quality and Health*

The aim of this research is to aid drinking water companies to evaluate the risks of hydraulic fracturing on drinking water sources with a focus on polar organic compounds due to their low removal efficiency during waste water treatment. Publicly available chemical assessments of hydraulic fracturing related waters are generally based on shale gas practices in the U.S., lacking information on other types of gas development also using hydraulic fracturing. This research fills this knowledge gap by presenting chemical and bioassay assessments of chemicals present in hydraulic fracturing related waters from a tight gas development in the Netherlands. Fracturing fluid, flowback water and groundwater from surrounding aquifers before and after the actual fracturing were analysed by means of HR LC-MS/MS, the Ames test and three CALUX bioassays (genotoxicity, oxidative stress response and polyaromatic hydrocarbon contamination). After sample enrichment a higher number of peaks can be found for both fracturing fluid and flowback samples. No clear differences in chemical composition were shown for the groundwater samples before and after hydraulic fracturing. Clear genotoxic and oxidative stress responses were found for the fracturing fluid and flowback samples. A preliminary suspect screening resulted in 25 and 36 matches in positive and negative ionization respectively with the 338 possible suspect candidates on the list. The results provide a scientific justification for the extensive measures currently in place related to the handling, transport and treatment of hydraulic fracturing related waters to avoid adverse environmental and human health impacts.

### 561 Ecotoxicity of Coal Seam Gas Hydraulic Fracturing Fluids

*D. Hobbs, R. Smith, Hydrobiology Pty Ltd*

With the increasing need for diversification of energy sources, the extraction of gas from coal seams has become a potential crossover energy provider in the move from coal to more sustainable energy sources for Australia and globally. As part of coal seam gas production, hydraulic fracturing of non or low producing wells is commonly undertaken. The toxicity of the individual major constituents that make up these fluids are generally well known, but the toxicity of hydraulic fracturing fluid as a mixture, or for many of the lesser/proprietary constituents is not well understood. The aim of this project was to understand the potential hazard of the hydraulic fracturing fluids in comparison with the in-situ formation waters to surface freshwater organisms in the gas tenements of the Surat and Bowen Basins of Central Queensland. The intent was to assess the ecotoxicity of the hydraulic stimulation fluids in the context of formation waters (pre-stimulation) and flowback water (produced water post-stimulation) from within the gas production areas. As a result, the program was designed in three phases. Phase 1 tested the formation water (water in the coal seam before stimulation) and source water (water used to formulate the hydraulic fracturing fluid) to establish background ecotoxicity. Phase 2 tested the incremental effect of hydraulic fracturing fluids mixed in laboratory water (of known ecotoxicity) and source water. Phase 3 tested the ecotoxicity of early and late stage flowback water from stimulated wells. The results of the project are presented along with the knowledge gained with regards to the hazard potential of the different fluid systems in use in Queensland at the time of the project.

### 562 Mahi mahi cardiomyocyte contractility and swim performance alterations following acute exposures to hydraulic fracturing flowback and produced water

*E. Folkerts, University of Alberta / Biological Sciences; R.M. Heuer, M. Grosell, University of Miami / Marine Biology and Ecology; G. Goss, University of Alberta / Biological Sciences*

In North America, horizontal hydraulic fracturing (HHF) is an emerging industrial practice used to extract oil and natural gas reserves. However, little investigation has been performed on the wastewater by-product of HHF activities: flowback and produced water (FPW). Chemical characterization has revealed numerous potential cardio-respiratory toxicants to exist within FPW. The aim of this study was to determine if acute FPW exposures alter cardio-respiratory responses in organisms which may encounter FPW in a spill event, namely fish. Using the pelagic and extremely aerobic *Mahi mahi* as a model organism to characterize changes to organismal cardio-respiratory parameters, isolated primary cardiomyocyte contractile properties and swim performance were analyzed in fish acutely exposed to different fractions of an FPW sample collected from a well 2 hours post-stimulation. Overall, cardiomyocytes displayed expanded contractive events following exposure to 2% FPW dilutions, while no effects associated to salt and osmotic stresses were found. These expanded sarcomere contractive effects following FPW exposure were primarily the result of decreased myocytic relaxation velocities back to sarcomere baseline distances following initial contraction. This effect increased exposed overall cardiomyocyte 50, 75, and 90% sarcomere return to repolarized/baseline distance times. To follow up on cardiomyocyte effects observed, we plan to perform acute whole organism *Mahi* exposures, and determine if swim performance and swimming respiratory is impacted following FPW exposure. This is one of the first studies to mechanistically investigate FPW effects on cardio-respiratory parameters at the cellular level, and determine that even at relatively low dilutions, FPW may elicit effects on fish cardio-respiratory systems. Our results validate the cardio-respiratory system as an important endpoint to consider for FPW risk assessment and adverse outcome pathway analysis, and may be a system viable for exposure marker development.

### 563 Early Life Effects of Produced Water on Menidia Beryllina Juveniles

*N.D. Denslow, K.J. Kroll, University of Florida / Physiological Sciences; E. Oruc, University of Cukurova / Department of Biology; M. De Maria Mulet, University of Florida / Physiological Sciences Department; E.C. Lopez Gonzalez, CONICET-UNL / Zoología aplicada Anexo Vertebrados FHUCUNL MASPyMA Santa Fe; A. González, Technological Institute of Chascomus; G. Saari, B.W. Brooks, Baylor University / Department of Environmental Science*

The composition of produced water from extraction of gas and oil from shale is complex, containing the chemicals that were added to make it work effectively plus hydrocarbons and salts that vary depending on the geochemistry of the site. Dissolved solids can range from 100 mg/L to 400,000 mg/L. We tested produced water from two wells in Texas that were from the same geological formation but differed in length of time of operation. One was in operation for 6 months and the other for 3 years. Raw waters were characterized for various chemical parameters and fractionated by solid phase extraction following usual EPA procedures for toxicity identification evaluations. Ten-day old Menidia beryllina juveniles were used in 72 h acute toxicity tests of both raw samples at 10%, 3%, 1%, and 0.3 % and SPE fractions at 100%, 10%, and 3% initial concentrations, respectively. Exposures were conducted using 8 juveniles/dish and 6 replicates per treatment. Fifty percent of the exposure solution was changed daily. The MEOH extracts of the fractionated water samples were the most toxic in terms of fish survival. Fish exposed to sublethal concentrations of the raw waters were evaluated for gene expression alterations using RNAseq. Cyp1A, StAR-related lipid transfer protein and long chain fatty acid transporters were among the genes most highly up regulated by the exposures while DNA repair protein RAD 51 was the

most down-regulated transcript. Gene set enrichment analysis suggests pathways related to cancer, cardiomyopathy, ROS generation and inflammation may be sublethal targets of the exposures.

**564 The effect of hydraulic flowback and produced water salinity on juvenile rainbow trout (Oncorhynchus mykiss)**

*P. Delompré, T. Blewett, University of Alberta / Biological Sciences; K. Snihur, University of Alberta; D. Alessi, University of Alberta / Earth and Atmospheric Sciences; C.N. Glover, Athabasca University; G. Goss, University of Alberta / Biological Sciences*

The extraction of hydrocarbons trapped in deep sedimentary deposits by hydraulic fracturing (HF) results in the formation of a wastewater named Flowback and Produced Water (FPW). This effluent is enriched in salts, organics and metals, and as such, is potentially toxic to aquatic biota. To date, the chronic effects of FPW exposure on fish have not been studied. Using an important model species, the rainbow trout, *Oncorhynchus mykiss*, the effects of exposure to either 3% FPW or its parallel saltwater-matched control solution (SW; i.e. salt component with no organic or metal toxicants present) were investigated. We measured the levels of plasma ions ($Na^+$, $K^+$, $Cl^-$, $Ca^{2+}$, $Mg^{2+}$), the activities of two key osmoregulatory enzymes, $Na^+$-$K^+$ ATPase and H-type ATPase. These biochemical endpoints were paired with gill histological analysis. Our results showed significant changes in gill morphology following exposure to FPW. These included the appearance of lamellar clubbing and an increase in the interlamellar cell mass. Although previous studies suggest changes in gill structure are driven by salts, no effects were observed in the SW group, suggesting an effect driven by either or both of the inorganic or organic toxicants. Furthermore, all effects on gill structure were only observed in 48-h exposed fish, with an apparent reversal of histopathology noted at later time points suggesting an ability of the fish to acclimate to FPW exposure. This study provides important insights for risk assessment, biomonitoring of FPW spills and minimization of post-spill environmental effects.

## Environmental Mercury Exposure: Mechanisms Associated with Its Immediate and Generational Effects

**565 Impacts of methylmercury on the physiology and behavior of a marine forage fish**

*X. Ye, N.S. Fisher, Stony Brook University / School of Marine and Atmospheric Sciences*

Methylmercury (MeHg) is a neurotoxin that is found in fish tissues and bioaccumulates in aquatic food webs over a wide range of geographic areas. The extent to which fish exposed to food with high MeHg concentrations are impacted is largely unknown, particularly in marine fish. Previous studies on freshwater fish have suggested that MeHg concentrations can cause adverse effects on growth, behavior, reproduction, and other sublethal endpoints. Some species of marine fish have high tissue concentrations of MeHg but effects on behavior and reproduction are little known. Here we examined effects of MeHg to a marine fish at the larval stage, the sheepshead minnow *Cyprinodon variegatus*. Fish were exposed to MeHg through diet or maternal transfer. For dietary uptake, larvae (ages 7 d to 5 weeks) were fed commercial fish flakes containing 0 or 4.8 ppm MeHg. Growth rates, respiration rates, and swimming activity were tested. For evaluating maternal transfer of MeHg, the female juvenile fish were fed control and MeHg-contaminated diets from an age of 3 -5 months. After exposing the fish to MeHg, female fish were paired with Hg-free male fish for spawning. We assessed egg production, the developmental success of embryos, hatching success of embryos, survival of larvae, growth of larvae and swimming behavior of larvae. Data to date suggest that dietary MeHg has no significant impact on larval fish growth and swimming activity (swimming speed, acceleration, active time and swimming distance) even when their tissue MeHg concentrations greatly exceed 0.3 ppm, the reported threshold for toxicity in freshwater fish. MeHg had a small but significant impact on the respiration rates of these fish. Decreased egg production was not observed after dosing juveniles. Future data gathered on developmental and hatching success of embryos, survival, and swimming of larvae will allow us to further evaluate the transgenerational effects of MeHg.

**566 Mercury bioaccumulation and body size influence peripheral blood leukograms in the Brown Watersnake (*Nerodia taxispilota*)**

*D.L. Haskins, M.K. Brown, University of Georgia / Savannah River Ecology Lab; M.A. Pilgrim, University of South Carolina Upstate / Department of Natural Sciences; K. Meichner, University of Georgia / Department of Pathology; R.M. Gogal, University of Georgia / Deptartment of Veterinary Biosciences and Diagnostic Imaging; T. Tuberville, University of Georgia / Savannah River Ecology*

Mercury (Hg) is a toxic heavy metal capable of polluting aquatic environments. In vertebrates, Hg can bioaccumulate, biomagnify, and maternally transfer to offspring. Exposure to Hg is known to negatively influence immune status, growth rates, reproductive success, behavior, and survival in numerous species. Risk assessments have investigated Hg bioaccumulation and effects in a variety of taxa, but little is known about its impact on reptiles. Brown Watersnakes (*Nerodia taxispilota*) exhibit traits that may put them at risk for accumulating significant amounts of Hg. They are long-lived (> 10 years), have a piscivorous diet, and are major predators in streams and rivers of the southeastern United States. This present study investigated total Hg (THg) levels in tail tips, the relationship between snout-vent length (SVL) and tail THg, and the impact of THg on peripheral blood leukocytes in *N. taxispilota* captured on the Savannah River. Snakes sampled in this study were downstream of a known Hg release source. Similar to other vertebrates, there was a significant increase in tail Hg levels with increasing snake size (ANCOVA, SVL: $F_{1,36} = 46.71$, $p < 0.001$). Although health criterion for THg in snakes is not available, mean THg levels in over half of snakes we sampled exceeded the USEPA's human health criterion for methylmercury in fish. Tail THg levels were inversely correlated with total white blood cell numbers ($r = -0.29$, $p = 0.078$). Further, as snake size increased, absolute basophil ($r = -0.43$, $p = 0.007$) and lymphocyte numbers ($r = -0.37$, $p = 0.023$) significantly decreased. These preliminary results from our first field season (2017) suggest a link between increasing THg levels in aging *N. taxispilota* with declining select leukocyte numbers, implying that these snakes, as they mature, may be more susceptible to infections as a result of continuous environmental and dietary Hg exposure. We will present our findings for both the 2017-2018 field seasons, adding blood THg and Se concentrations – allowing us to explore the relationship between Hg and Se concentrations in *N. taxispilota*.

**567 Systematic Review of Mercury Exposures Worldwide – Findings from the 2018 UN Global Mercury Assessment**

*N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; M. Horvat, Jozef Stefan Institute; D. Evers, Biodiversity Research Institute; I. Zastenskaya, WHO European Centre for Environment and Health; P. Weihe, The Faroese Hospital System / Department of Occupational Medicine and Public Health; J. Tempowski, WHO*

The Minamata Convention on Mercury Pollution provides a mandate to take action against global mercury pollution. However, our knowledge of mercury exposures around the world remains limited. As part of the 2018 UN Global Mercury Assessment, WHO led the current study to increase worldwide understanding of human exposures to mercury by collating and analysing mercuryconcentrations in biomarker samples via a systemic review. A systematic search of the peer-reviewed literature was performed with several a priori search strategies set. The overall work captured 424,884 mercury biomarker measures taken from 336,015 individuals represented in 312 articles from 67 countries. We identified four populations of concern for which there exist a relatively robust dataset: 1) Arctic populations (mainly Inuit) who consume fish and marine mammals; 2) tropical riverine communities (especially Amazonian) who consume fish, and in some cases may be exposed to mining operations; 3) coastal and/or small-island communities who are avid seafood consumers; and 4) individuals who either work or reside amongst artisanal and small-scale gold mining (ASGM) sites. Individuals in select background populations worldwide with insignificant exposures to mercury sources have blood mercury levels that generally fall under 5 mg/L and urine mercury levels that fall under 3 mg/L. This systematic review documents that all people are exposed to some amount of mercury, and that there is great variability in exposures around the world. This type of information is critical in helping understand exposures particularly in light of the Minamata Convention on Mercury Pollution and certain stipulations within the Convention text (e.g., can inform Article 22's effectiveness evaluation especially for vulnerable populations; gauge changes over geographic space and time).

**568 Selenium Availability in Freshwater Fish is Inversely Related to Methylmercury Bioaccumulation and Toxicity**

*N. Ralston, Sage Green NRG / Earth Systems Science and Policy; L. Raymond, Translational Medicine Independent Research Consultants*

Based on the biochemical mechanisms of mercury (Hg) toxicity, concomitant assessments of selenium (Se) intakes are required for reliable assessments of risks potentially associated with Hg exposures. This consideration is especially true in regions that are Se-poor or exposed to high Hg inputs. In particular, subsistence consumers of high methyl-Hg ($CH_4Hg^+$), low-Se freshwater fish may be at greater risk than would have been assumed based on earlier assumptions that did not consider Hg's biochemical mechanisms of toxicity. Because $CH_4Hg^+$ is uniquely able to: 1) diminish maternal Se redistribution across the placental barrier, 2) decrease Se-transport across the blood-brain barrier, and 3) irreversibly inhibit selenoenzyme activities which are required to prevent and reverse oxidative damage in brain tissues, Se status is a pivotal consideration in $CH_4Hg^+$ risk assessments. The Hg and Se content data of ~5,000 freshwater fish from North American watersheds were compiled for calculation of their Health Benefit Values (HBVs). There was a strong inverse relationship between environmental Se availability and $CH_4Hg^+$ contents of the fish, especially among aquatic apex predators. Due to the high binding affinities between Hg and Se, the same chemical reactions responsible for the irreversible inhibition of Se-dependent enzymes, formation of insoluble HgSe, and the physiological consequences of high $CH_4Hg^+$ exposures were predicted to result in an inverse relationship between Hg and environmental Se availability. In the presence of adequate Se, Hg that is retired as HgSe cannot bioaccumulate in aquatic food webs. However, in the absence of adequate Se, there is no Hg retirement, and increased $CH_4Hg^+$ bioaccumulation should occur. This study found the highest fish Hg concentrations were observed in watersheds with the poorest Se availability. Although increased exposure from eating such fish will increase risk, the fact that Se-poor consumers will be more vulnerable to the effects of high $CH_4Hg^+$ exposures accentuate the risks of adverse effects. Thus, increased $CH_4Hg^+$ exposures in areas where environmental Se is poorly available may result in an adverse synergy with the potential to cause far greater impairments to fetal neurodevelopment than those predicted by earlier $CH_4Hg^+$ risk assessment criteria. Increased monitoring is required to identify regions that are likely to have subsistence populations at risk.

**569 Wildlife as a Surrogate Indicator for Impacts of Mercury on Ecosystem Health**

*L. Chan, University of Ottawa / Biology*

Methylmercury (MeHg) is a cause for concern for the health of humans, wildlife, and the ecosystem due to its known immunotoxic, nephrotoxic and neurotoxic effects. MeHg bioaccumulates and biomagnifies in the aquatic food web putting the organisms higher in trophic position at greater risk of mercury exposure. The relationships between mercury (Hg), MeHg, inorganic Hg (iHg), and selenium (Se) exposure, and neurochemical and molecular biomarkers in beluga whales (Delphinapterus leucas (Pallas, 1776)) were characterized. Samples were collected in 2008 (n = 20) and 2010 (n = 15) in the Canadian Arctic from hunter-harvested beluga whales. Total Hg concentrations in the temporal cortex and cerebellum were 21.0 ± 22.6 mg kg−1 dry weight (dw) and 14.9 ± 18.9 mg kg−1 dw, respectively. Monoamine oxidase (MAO) activity was predicted by MeHg and the molar ratio of total Hg to Se (Hg:Se, $p < 0.05$); MAO-A mRNA transcription levels were predicted by iHg and Se ($p < 0.05$). Muscarinic AChR binding was predicted by MeHg ($p < 0.05$) and Hg:Se molar ratio ($p < 0.05$), and mRNA transcription levels of mAChR m1 was predicted by the Hg:Se molar ratio ($p < 0.05$). These results suggest that the cholinergic and dopaminergic signaling pathway in Eastern Beaufort Sea beluga whales may be sensitive to MeHg exposure. The response of beluga whales to MeHg exposure at a physiological and population level remains to be elucidated.

**570 Improving the Utility of Tetragnathid Spiders as a Bioindicator: Implications for Mercury, Methyl-Mercury, and Stable Isotopes**

*G. Beaubien, C. Olson, R.R. Otter, Middle Tennessee State University / Biology*

Tetragnathid spiders (Family: Tetragnathidae, Genus: *Tetragnatha*) found in riparian habitats feed primarily on emergent aquatic insects and have recently been used as bioindicators of sediment contamination and insect-mediated contaminant flux. To better understand the utility of tetragnathids as bioindicators, we designed a two-tier study in Tennessee's Appalachian Mountains. We first investigated the inter-site differences of whole-body tetragnathid stable carbon ($\delta^{13}C$*) and nitrogen (*$\delta^{15}N$*) isotopes, as well as*total mercury and methyl-mercury concentrations. We then investigated the utility of different tissues (legs, opisthosoma, and prosoma) to represent whole-body $\delta^{13}C$ *and* $\delta^{15}N$*,*and whether sex effected total mercury concentrations. Analysis of δ13C and δ15N revealed site-specific isotopic signatures, but tissue samples (legs, *prosoma* and *opisthosoma*) were not significantly different, and all tissues were representative of whole-body composites. Results showed that total mercury concentrations were different among sites, but not between sexes. There was no difference in the MeHg concentrations; however, the percentage of total mercury that was methyl-mercury ranged from 17-47 %-MeHg – well below previously reported values of ~70%-MeHg.

**571 Using *Caenorhabditis elegans* to explore novel pathways involved in methylmercury's effects on cellular energetics and neurodegeneration**

*M. Aschner, S. Caito, Albert Einstein College of Medicine / Molecular Pharmacology*

Methylmercury (MeHg) is a major environmental contaminant that has been linked to developmental and neurological disorders. With the aging population, new concerns have arisen on how MeHg may affect aging and age-related diseases such as Parkinson's disease (PD). Studies of MeHg toxicity have traditionally been performed in mammalian systems, which are both costly and complex for age-related studies. The soil-dwelling nematode, *Caenorhabditis elegans*is a valuable alternative to both rodents and mammalian cell culture for studying the effects of MeHg on age-related conditions. *C. elegans* has a short lifespan, well characterized genetics, highly genetically manipulable, and highly homologous to humans. Taking advantage of the system, our lab has shown that MeHg behaves similarly in nematodes as in mammals, entering cells through amino acid transporters, eliciting oxidative stress, leading to altered gene expression and dopamine (DA) neurotransmission. Studies utilizing GFP-expressing transgenic *C. elegans* can directly investigate the role of specific proteins in neuronal function by assaying for neuron-specific morphology and behaviors. Using *C. elegans* expressing MCherry under the promoter for the DA transporter, we have found that MeHg alters cellular nicotinamide adenine dinucleotide ($NAD^+$) levels leading to both altered dopaminergic (DAergic) cell morphology and behavior as measured by the basal slowing response. Supplementing the worms with excess $NAD^+$attenuates the effects of MeHg on both behavior and DAergic cell morphology. Alterations of cellular $NAD^+$by MeHg may have profound affects on cells due to the inhibition of sirtuins, NAD-dependent enzymes involved in aging and epigenetics. Supported in part by a grant from the National Institute of Environmental Health Sciences (NIEHS) R01 ES07331.

**572 Abnormal gene expression leading to neurobehavioral abnormalities is induced by methylmercury exposure of grandparents**

*M.J. Carvan, J.K. Larson, R. Klingler, University of Wisconsin Milwaukee / School of Freshwater Sciences*

Methylmercury (MeHg) is a ubiquitous environmental neurotoxicant. Developmental exposure of zebrafish to MeHg is known to alter their neurobehavior in a manner similar to other vertebrates. The current study investigated the direct and transgenerational effects of MeHg, at tissue doses similar to those detected in exposed human populations, on sperm epimutations (i.e., differential DNA methylation regions [DMRs]), neurobehavior (i.e., visual startle and spontaneous locomotion), and transcriptomics in zebrafish, an established human health model. F0 generation embryos were exposed to MeHg (0, 1, 3, 10, 30, and 100 nM) for 24 hours ex vivo. F0 generation control and MeHg-exposed lineages were reared to adults and bred to yield the F1 generation, which was subsequently bred to the F2 generation. Direct exposure (F0 generation) and transgenerational actions (F2 generation) were then evaluated. Hyperactivity and visual deficit were observed in the unexposed descendants (F2 generation) of the MeHg-exposed lineage compared to control. An increase in F2 generation sperm epimutations was observed relative to the F0 generation. Investigation of the DMRs in the F2 generation MeHg-exposed lineage sperm revealed associated genes in the neuroactive ligand-receptor interaction and actin-cytoskeleton pathways being effected, which correlate to the observed neurobehavioral phenotypes. Developmental MeHg-induced epigenetic transgenerational inheritance of abnormal neurobehavior is correlated with gene expression changes and sperm epimutations in F2 generation adult zebrafish. Therefore, mercury has the ability to promote the epigenetic transgenerational inheritance of disease in zebrafish, which significantly impacts its environmental and ecological health considerations. Further study of the transgenerational health effects of MeHg is required to better understand the risks for exposed populations, which, if transgenerational effects are ignored, are dramatically underestimated.

## Plants in Environmental Risk Assessment: Assessing and Predicting the Effects of Chemicals on Plant Communities

**573 A field study method as a potential higher tier option to refine risk assessment for non-target terrestrial plants**

*R.J. Isemer-Kellner, Bayer Ag; I.M. Rodea-Palomares, Bayer CropScience LP / Environmental Toxicology & Risk Assessment; C. Mihan, Bayer CropScience AG / Ecotoxicology; D. Jans, Bayer CropScience AG; P. Sowig, Bayer AG Crop Science Division; T. Hall, Bayer / Environmental Toxicology and Risk Assessment; V. Ducrot, Bayer Ag / Environmental Safety Ecotoxicology*

During the regulatory approval process for pesticides, potential side-effects to non-target terrestrial plants (NTTP) are assessed. Routine testing with NTTPs is done in standardized greenhouse studies under conservative assumptions. If the obtained results show a concern for NTTPs, higher tier testing may be needed to assess whether this concern may occur under more realistic conditions in the field. So far no agreed NTTP field study method has been established. Based on three pilot studies (2014-2016), we developed a method for conducting higher tier field studies with NTTPs using commercially available seed mixtures as the source for establishing study sites (posters SETAC Europe 2016&2017). In these studies, it was found that both seed mixture and growth area (including weather, soil etc.) greatly influence the distribution of species and homogeneity of replicates. Specific farming measures (e.g. sequential plowing prior to seeding) were defined to overcome the out-competition of the sown species by other species emerging from the soil seed bank. Here we present results of a field study performed in Germany during 2017 according to our established method. Effects of a sulfonyl-urea herbicide on 11 plant species sown as a seed mixture were evaluated throughout the growing season (May to September). Three herbicide rates plus a control were applied to four replicate plots each. Vegetation cover according to the Londo scale, dry biomass of total vegetation, symptoms of phytotoxicity as well as BBCH stage of the sown species were regularly assessed. Although the utilized farming measures reduced emergence of plant species from the soil seed bank, their occurrence seems to be unavoidable. Therefore, the spontaneously emerged species were included in the vegetation coverage and biomass assessments. The assessed endpoints and species showed different responses to the tested herbicide, e.g. we could estimate NOECs for coverage during early assessments, but not for biomass, while during posterior assessments, NOECs could be derived for biomass. As it is expected for a more realistic higher tier testing method, variability was high for some endpoints e.g. the treatments` coverage for *Borago officinalis* was in the control range at most assessments. Effects of the herbicide in field conditions were less pronounced than predicted by corresponding greenhouse studies confirming the suitability of the study for refining the risk assessment for NTTPs

**574 A comparison between vegetative and reproductive endpoints for two non target plant studies with non-crop species in greenhouse and field**

*S. Knaebe, EAS Ecotox GmbH / Ecotox Field; A. Duffner, Eurofins Agroscience Services Ecotox GmbH / Terrestrial Ecotoxicology Lab; D. Ripperger, P. Mack, Eurofins Agroscience Services Ecotox GmbH*

Terrestrial plants are providing a broad spectrum of ecosystem services such as the provision of e.g. food and natural medicines or the regulation of air quality. Plants in the agricultural ecosystem can be divided into three basic groups: crop plants, target plants for herbicides (weeds) and non-target terrestrial plants (NTTPS). The only refuges for NTTPS in intensively used agricultural areas are often field margins representing the majority of semi-natural habitats. Since agriculture is the dominating land-use in the temperate zone protection of non-target plants is a regulatory aim. Using herbicides to reduce weed competition in agricultural areas can adversely affect non-target terrestrial plants growing at field margins.For a more realistic assessment of effects there are several suggestions to include also non-crop species in the testing scheme from the list provided in OECD guidelines (OECD 208 and 227) and to assess the life-cycle with flowering and seed production. In this work two separate studies are compared to find out if non-crop species tested in greenhouse and in a field result in a comparable outcome. The experimental design used in both studies consists of one control and four application rates with the same herbicide product. In the greenhouse (OECD 227) 6 replicates per rate were used while in the field 8 replicates were used to account for the higher variability in the field. Furthermore, in the greenhouse species were grown individually while the field study consisted of plant communities. The four rates included the field rate down to a 3% drift rate. Assessed were biomass and plant height at the vegetative and generative phase of the plants. The number of flowers and seeds and germination of the harvested seeds were assessed for selected species to evaluate differences in flowering and germination. Furthermore, in the field study effects on plant community were assessed with multivariate analysis. To make results more comparable MDD were calculated for the individual endpoints. Since the same rates and species are used it is possible to investigate the effects of pesticides to specific plant species in both scenarios and to confirm that a higher TIER approach is also useful for plants.

**575 Testing the emergent macrophyte, *Glyceria maxima* in a water-sediment system: Progress of ring-tests with Isoproturon and Imazapyr**

*J. Davies, Syngenta / Environmental Safety; G.P. Arts, Wageningen University and Research / Wageningen Environmental Research (Alterra) Wageningen; J. Kubitza, BASF; K. Kuhl, Bayer AG – Crop Science Division; M. Ratte, ToxRat Solutions GmbH & Co. KG*

Under EU pesticide regulation, regulatory tests are required for the aquatic macrophyte, *Lemna*, and two algal species for herbicides and plant growth regulators. Data requirements introduced under EU Directive 1107/2009 stipulate that further tests may be required for compounds which show selectively higher toxicity to either dicotyledonous or monocotyledonous plant species in terrestrial plant tests. In these cases, the recommended dicot and monocot species are *Myriophyllum* and *Glyceria*, respectively. OECD Test Guideline 239 for testing *Myriophyllum spicatum* in a water-sediment system was adapted to facilitate growth of the emergent, reed grass, *Glyceria maxima*, and ring-tested in 13 laboratories during 2016 and 2017 with the herbicide, isoproturon. Results from this ring-test were used to adapt the test protocol in terms of plant propagation recommendations, test system specification, test duration, assessment parameters and draft validity criteria. The revised protocol was then used in a second ring-test with the herbicide, imazapyr during the summer of 2018. Results of the isoproturon ring-test will be presented alongside progress on the second ring-test with imazapyr.

**576 Experimental Design and Model Selection for Ecotox Risk Assessment**

*J.W. Green, DuPont / Data Science and Informatics*

Recent experience with regulatory requests for re-analysis of older studies using newer statistical methodology has resurrected an old statistical issue of designing a study to fit its objectives and the dangers of imposing a statistical structure on data not fit for purpose. There is a continual need to update statistical methodology as new ideas arise and software to implement these methods become available. Problems can arise when new methods are imposed on old experimental designs. Imagine buying a plot of land with a small cottage. If we tear down the cottage, but leave the cellar and foundation, and then build a mansion in its place but based on the existing foundation, the resulting structure can be unstable and severely restricted in functionality. This presentation will explore the relationship between experimental design and the type of statistical model that can be fit to the resulting data and endpoints that can be estimated or determined from the model. In some instances, newer methods can be applied without problem to existing data. In other cases, existing data cannot support newer methods. It is important to understand the data requirements of the methods or models we intend to use. The size effect that can be estimated or detected is critically important and is strongly related to experimental design and biological variability. There is a model underlying every statistical test used to derive a NOEC or estimate an ECx. The basic statistical model for a simple toxicity experiment is given by $Y_{ij}=\mu_i + e_{ij}$, where $\mu_i$ is the expected mean response in the $i^{th}$ concentration, and the $e_{ij}$ are independent random errors, usually assumed to be identically distributed. What distinguishes one model from another are what distribution is assumed for the errors or responses and what restrictions or assumptions are placed on the treatment means, $\mu_i$. It is possible to determine the size effect that can be estimated or detected from a given dataset and it depends largely on experimental design and response variability. Statistical models used for hypothesis testing or regression estimates have data requirements. Model assessment tools are well established and should be used in fitting models to ecotoxicity data. Ignoring these tools or model requirements can lead to poorly estimated effects and misleading results. Understanding these concepts enables the scientist to make sound assessments of the data collected.

**577 Biochar Enhances Seed Germination in a Legacy Mining Soil**

*D. Olszyk, USEPA / NHEERL / WED; T. Shiroyama, Senior Environmental Employment Program; R. Coulombe, G. King, M. Plocher, CSS Inc.; J. Novak, USDA / ARS / CPRC; M. Johnson, USEPA*

Biochar, the carbon-rich material remaining after pyrolysis (heating in low oxygen atmosphere) of cellulosic feedstocks, has the potential as a soil amendment to sequester contaminants, improve soil water-holding capacity, and increase nutrient retention thereby enhancing soil conditions to benefit plant growth. Thus the benefits of biochar could enhance the establishment and growth of plants for mine site revegetation. We evaluated the potential for different biochar types and application rates on grassland species being considered for revegetation of land affected by historic lead and zinc mining in southwestern Missouri. We used a seed germination test to determine the effects of biochar on seed germination and early seedling growth for six plant species, as well as key soil characteristics, pH and EC for plants growing in a lead/zinc mine soil, with the lead-containing wastes removed. This study was a preliminary screening of plants growing on amended mine soil before full-fledged greenhouse and field studies. Plant species were *Andropogon gerardii* (ANGE, big bluestem), *Elymus Canadensis* (ELCA, Canada wildrye,), *Elymus virginicus* (ELVI, Virginia wildrye), *Panicum virgatum* (PAVI, switchgrass), *Schizachyrium scoparium* (SCSC, little bluestem), and *Sorghastrum nutans* (SONU, Indiangrass). Biochar was made from barnyard manure (BM), yard debris (YD), hardwood pellets (HP), cedar wood (CW) and prairie hay (PH) pyrolyzed at 350, 500 and 700 °C, and applied at rates of 1, 2.5 and 5% by weight. While there were few effects of biochar on seedling emergence, early seedling growth measured as dry weight was significantly increased by a number of the biochars. Species responded differently, as growth of PAVI and SONO seedlings growth was increased by nearly all biochars, ELCA and ELVI growth was increased by many biochars, and ANGE and SCSC growth was largely unaffected by biochar. Soil pH was increased by nearly all biochars, and soil extractable phosphorus (EP) was increased by many of the biochar treatments, but especially by the higher nutrient content BM and PH biochars. Soil electrical conductivity (EC) was increased primarily by BM and PH. Nearly all effects of biochar on pH, EP and EC were greatest at the 5% biochar application rate. This study indicated the potential for biochar to enhance early seedling growth in mine affected soils, largely by improving soil chemical characteristics.

**578 Microplastic exposure elicits responses of spring onions and associated soil microbiomes**

*A. de Souza Machado, Freie Universität Berlin / Institute of Biology; C. Lau, J. Roy, F. Degrune, Freie Universität Berlin; W. Kloas, Leibniz-Institute of Freshwater Ecology and Inland Fisheries; E. Faltin, Freie Universität Berlin; R. Becker, BAM Federal Institute Materials Research and Testing; M.C. Rillig, Freie Universität Berlin*

Microplastics are among the most long-lasting contaminants, and this novel stressor might cause several ecological impacts on marine and fresh waters. However, there is a lack of information on the risks of this pollution on land. Thus, it is highly relevant to unravel potential effects of microplastics on processes of terrestrial function. We contaminated a loamy sand soil with 6 different types of microplastics (polyester fibers, polyamide beads, and 4 micro-fragment types: PE-HD, PET, PP, and PS), plus a control without plastic addition. Polyester fibers were added to 0.4% of soil weight, while other plastics were added to 2.0% of soil weight. Each treatment included 12 replicates of a single microplastic type mixture with soil. Soil was kept in glass beakers in the dark for 2 months at 90% water holding capacity for soil microbiome acclimation. Then, we introduced in half of experimental replicates (N=6) seedlings of *Allium fistulosum* (spring onion) that had been germinated under sterile conditions. After a 2-months growth period, the evapotranspiration rates were assessed. The spring onions were then harvested for measurement of plant biomass (above-ground, onion bulb, and roots), and root traits. We also quantified proxies of soil function (water stable aggregates, soil structure, and bulk density). Finally, we assessed microbiome diversity and function via soil microbial activity (FDA), root mycorrhizal colonization (root staining), and DNA sequencing of bulk soil and rhizosphere bacteria, fungi, and cercozoa. No significant lethal toxicity could be observed for this plant model in response to any of the plastics. However, diverse changes on plant-soil responses were observed in case of exposure to polyester fibers and polyamide beads. The fibers increased below-ground biomass (root and onion bulb), while beads increased 3-fold above-ground biomass and significantly decreased above-ground/ root ratios. These changes were accompanied by significant effects on soil biophysical environment, microbial activity, and microbiome diversity. Our unprecedented results highlight the potential of microplastics to trigger environmental change in terrestrial systems via mechanisms other than direct toxicity. Considering such effects and the potentially near-permanent widespread terrestrial contamination, ecologically significant baseline shifts caused by microplastics in soil systems and their plant holobionts cannot be ignored.

**579 F1 seed germination and seedling growth of rice (Oryza sativa japonica) exposed to arsenic and copper oxide nanoparticles**

*J. Liu, Baylor University / Department of Environmental Science; K. Wolfe, Baylor University; G.P. Cobb, Baylor University / Department of Environmental Science*

An F1 rice (*Oryza sativa japonica*) seed germination and seedling growth test was conducted to investigate the intergenerational effect between F1 and F0 with different treatments of arsenic (As) and copper oxide nanoparticles (nCuO). F0 rice seeds were exposed to As (0 and 10 mg/kg sand) and nCuO (0, 0.1, 1.0, 10, 50, 100 mg/L) in a whole life cycle greenhouse study. F1 seeds were harvested from the 12 treatments (2 levels of As × 6 level of nCuO) and exposed again to the same treatments as F0 seeds in addition to control and As alone treatment. F1 tests were conducted for 18 days in an incubator with temperature controlled at 25 ± 1 ? during daytime (16 h) and 20 ± 1? at night (8 h). F1 seed germination was influenced by treatments that F0 seeds received ($p < 0.05$). Seeds produced from treatment with nCuO at 50 mg/L had the lowest germination percentage ($p < 0.05$). Neither As nor nCuO exposure individually influenced F1 seed germination, but the interaction of As and nCuO differentiated the germination at various concentrations of nCuO ($p < 0.05$). F1 seedling shoot length (SL), root length (RL), and the number of root branches (NRB) were all affected by different F0 treatments ($p < 0.001$). The SL and RL of F1 seedlings were all decreased by F1 As alone treatment compared with control ($p < 0.001$), whereas the NRB was increased by F1 As alone treatment ($p < 0.001$). The F1 seedling SL was mainly decreased by F1 exposure to nCuO ($p < 0.001$). The interaction of As with nCuO at low concentrations (0, 0.1 and 1.0 mg/L) of nCuO decreased the F1 seedling SL, and increased by the interaction at high concentrations of nCuO (50 and 100 mg/L) ($p < 0.001$), corresponding to the same nCuO concentration without As. The F1 seedling RL were all decreased by As and nCuO, and the interaction of the two toxicants was significant ($p < 0.001$). The NRB was primarily increased by As treatment ($p < 0.01$). To conclude, transgenerational effects were observed on both germination and early seedling growth of rice. Additional respective exposures of F1 seeds to As or nCuO did not affect seed germination but affected the seedling growth. The interaction of As and nCuO was significant on seed germination, the SL, and RL.

**580 Translocation of [14C] Plant Protection Product in Tomato: Evaluation of Foliar and Soil Application by Autoradiography**

*S. Freedlander, Smithers Viscient, LLC / Environmental Fate and Metabolism; S. Rao, Gowan Company / Regulatory; K. Malekani, S. Kang, Smithers Viscient / Environmental Fate and Metabolism*

Once applied to a plant, chemical residues have the potential to move to other plant tissues via phloem and xylem. This translocation can affect pollinating insects and consumers of the plant tissues. In this study the translocation of a plant protection product to various tomato tissues (flower, leave, stem, and root) was evaluated. Tomato plants of a common commercial variety at the BBCH 51 stage were split into three groups: an untreated control group, a foliar application group, and a soil application group. A suspension formulation of [$^{14}$C]active ingredient of a plant protection product was applied in a single application at a rate of 0.50 kg a.i./ha by foliar application and soil application to the corresponding groups. Leaves, stems, and flowers were harvested at 1, 2, 4, 6, and 8 weeks after application and root tissue was harvested at 8 weeks after application. At each sampling interval, the collected tissues were analyzed for total radioactive residue (TRR) by combustion analysis and autoradiography by phosphor-imager analysis. Select tissue samples were extracted and analyzed by HPLC with radiochemical detection (HPLC-RAM). The combustion results demonstrated that the TRR were higher in soil application tissues than in foliar application tissues for all tissue types at all sampling intervals. The autoradiographs were correspondingly darker in the soil application tissues. HPLC-RAM analysis indicated that the majority of extracted residues were metabolites of the active ingredient. These data indicate foliar application resulted in reduced translocation of this active ingredient of a plant protection product – and metabolites thereof - when contrasted with soil application. In conclusion, translocation can be effectively evaluated by autoradiography. This procedure can be incorporated into a conventional plant metabolism study, and can provide valuable information to better assess the potential exposure of pollinating insects and consumers to plant protection product residues.

## Bridging the Gap Between Toxicity Method Challenges and Regulatory Compliance for Effluent and Ambient Toxicity Programs

**581 NPDES permitting – How Permit Language Affects Laboratory Performance**

*V.A. Lozano, USEPA / Wastewater Unit; S. Zavala Bogdan, USEPA, Region 6 / NPDES Permits and TMDL Branch*

National Pollutant Discharge Elimination System (NPDES) permitting regulations under the Clean Water Act (CWA) have been in place since the mid 1980's. As part of these regulations, Whole Effluent Toxicity (WET) testing has been utilized as a tool in NPDES permitting to protect the narrative water quality standards on receiving streams and prevent the discharge of toxics in toxic amounts. The science utilized in developing the WET methods is well understood in the laboratory setting; however, the transfer of technical knowledge, test nuances, method variability and the proper implementation of these methods, as prescribed in NPDES permits, is not consistent across the nation. WET laboratories, national laboratory accreditation programs, and regulatory staff have been working to standardize approaches but more work is needed. This session will provide the EPA NPDES permitting regulatory perspective on the inclusion of WET requirements in permits, the lack of specificity needed to control WET test requirements, and the troubles caused by minimal permitting controls. Additionally, regulatory resources and options will be discussed to aid in the advancement of the science from the public perspective as approached through the provisions provided under the CWA. *This session will provide direct implementation (DI) permitting experience as viewed by the EPA regional offices.*

**582 Update on the WET Method Errata and Data Questions for Whole Effluent Toxicity Test Methods**

*T.J. Norberg-King, USEPA / NHEERL / Mid-Continent Ecology Division*

The Clean Water Act sets the goal of maintaining the chemical, physical, and biological integrity of the Nation's waters and the national policy, and with that goal, the discharge of toxic pollutants in toxic amounts is prohibited. The use of aquatic toxicity testing, such as whole effluent toxicity (WET), under the National Pollutant Discharge Elimination System (NPDES) permits program, is an important component of the Environmental Protection Agency's integrated approach to water quality-based toxics control, along with aquatic life chemical-specific criteria and biological assessments. Over the years, continued toxicity testing method modifications, laboratory accreditation, increased training, and technical resources have abounded for toxicity tests with the widespread use of the promulgated methods. In whole effluent testing, the use of the toxicity test has become a valuable component of most water quality monitoring programs, and the use of standardized acute and sublethal freshwater and marine methods specify test acceptability criteria (TAC) for survival, growth, reproduction and provide specific testing procedures. Acute toxicity of effluents appears to have decreased since the WET testing has been required. Errata have been periodically published, and a summary of the errata will be presented. Data reviews of test results have shown laboratories interpret the required procedures differently. For example, while the time frame to end the chronic *Ceriodaphnia dubia* test is when 60% of the controls have three broods, some labs do not terminate until 80% have the third brood. Interpretation guidance is needed for these types of issues, and by strengthening the knowledge exchange between practicing laboratories, more consistent interpretations should be able to be made. Additional species are needed for effluent assessments, and methods are being assessed for two sensitive species, e.g., mayflies and mussels. This presentation will discuss the progress that has been made in the conduct and application of these tests and changes made in EPAs errata, along with recommendations to improve the quality and utility these tests, including suggestions for laboratory proficiency guidelines. *This abstract does not necessarily represent the position or policy of the USEPA.*

**583 Improving the Laboratory Accreditation Process for WET Methods: Progress of the NELAC's Whole Effluent Toxicity (WET) Testing Expert Committee**

*T.J. Norberg-King, USEPA / NHEERL / Mid-Continent Ecology Division; R.B. Naddy, TRE Environmental Strategies; P.F. De Lisle, Coastal Bioanalysts Inc; E.G. Briggs, Bio-Analytical Laboratories, Inc.; E. West, Louisiana Environmental Laboratory Accreditation Program, LDEQ Northwest Regional Office / Technical; S. Rewa, Environmental Resources Management*

Fostering the generation of environmental data of known and documented quality through an open, inclusive, and transparent process that is responsive to the needs of the community is a mission of *The NELAC Institute* (TNI) with the National Environmental Laboratory Accreditation Program (NELAP) (www.nelac-institute.org). TNI envisions a national accreditation program, whereby all entities involved in the generation of environmental measurement data within the United States are accredited to one uniform, rigorous, and robust program that has been implemented consistently nationwide and focuses on the technical competence of the entity pursuing accreditation. With NELAP concensus standards of best professional practices, the quality and reliability of environmental data used by federal and state agencies will be improved. Many fields of accreditation are available: metals, nutrients, oxygen demands, semivolatile organic compounds, general chemistry I and/or II, microbiology, asbestos, synthetic organic chemicals, volatile organic compounds, radionuclides, whole effluent toxicity testing, hazardous waste characterization, petroleum hydrocarbons, perchlorate, and/or basic environmental laboratory. As such, the TNI Whole Effluent Toxicity (WET) Testing Expert Committee serves to update and maintain the whole effluent toxicity testing standard while providing technical assistance on issues related to whole effluent toxicity, develop tools to aid implementation, and to facilitate the implementation of the TNI Standard. The workgroup provides guidance for standardizing test conditions required for proficiency testing (PT)/ Discharge monitoring report quality assurance (DMRQA) studies performed under the auspices of the USEPA, rather than the current practice of conducting multiple tests using different NPDES permit test conditions, so that a statistically significant number of comparable sample results are available. Another recommendation was to improve the statistical power and evaluation of WET data sets and results in PT/DMRQA studies by selecting one statistical method to calculate the test endpoint and eliminating the use of hypothesis test endpoints. With experts, the programs for TNI on WET testing methods, quality control and data interpretation is updated. In this presentation, we will highlight some of the solutions to these issues as recommended by TNI WET workgroup. *This abstract does not necessarily represent the position or policy of TNI or the USEPA.*

**584 The Value and Challenges of WET as a Compliance Tool – Part II**

*R.B. Naddy, TRE Environmental Strategies; D.A. Pillard, TRE Environmental Strategies / Environmental Toxicology*

Why is it that an unfavorable analytical value is more acceptable by a permit-holder compared to an unfavorable whole effluent toxicity (WET) value which is often viewed with disbelief and doubt? In addition to a general mystery among some permit holders about the purpose of WET and how, or why, it applies to permit compliance, an oft-heard criticism of WET (even though it has been around for decades) is: there is very little if any progress or development of methods. This is in contrast to analytical methods, which appear to be more fluid. While being able to measure the concentration of a chemical in the environment is important, shouldn't equal importance apply to methods that assess whether that chemical is bioavailable to organisms in the environment? In this paper we will present numerous factors that contribute to the skepticism some have for WET. These include accuracy and precision of test data (e.g., how repeatable and useable are these data), representativeness of test species (there are few species and test methods), and regulatory application of WET results (what constitutes a 'toxicant'?) to name a few. Among the discussion points presented is the ultimate need for all interested parties to cooperatively participate in actions that will help address some of these WET shortcomings, and further refine the WET tool to its fullest potential. Only then will we be able to bridge the gap between WET method challenges and regulatory compliance.

**585 Strategies for ecotoxicology assessment of physical, biological, and chemical stressors in ambient waters**

*W.L. Goodfellow, Exponent, Inc. / Ecological and Biological Sciences Practice; S. Paulsen, Exponent Inc. / Environmental and Earth Sciences*

Compliance parameters for NPDES permits typically employ a suite of physical, chemical, and ecotoxicological tests to determine whether an effluent discharge has an adverse impact to the receiving waterbody. Traditionally, acute and chronic toxicity testing have been used for assessing whole effluent toxicity (WET) to fishes, invertebrates, and plant surrogate test organisms in laboratory exposures using prescriptive methods. However, addressing impacts observed in the environment often requires consideration of physical stressors, biological toxins (e.g., harmful algae blooms), and chemical stressors in ambient waters and sediments and thus often requires non-traditional tests or the application of traditional tests in non-traditional manners. This presentation will provide strategies that have been used successfully to assess the impacts of physical, biological, and chemical stressors in ambient waters and sediments. These strategies focus on determining causation of a specific stressor(s) and use of a weight-of-evidence approach in field and laboratory assessments of ambient waters and sediments.

**586 *C. dubia* reproduction impairment in low conductivity culture water**

*M. Vasi Stillway, University of California, Davis / VMAPC; C.A. Irvine, RBI / Ecosystem Services; S. Teh, University of California, Davis / School of Veterinary Medicine*

The chronic toxicity test method for *Ceriodaphnia dubia* is widely used for ambient surface water toxicity testing, regulatory compliance, or other programs. The USEPA test methods (i.e., method 1002.0) are relatively clear; however, interpretation of results is less clear when secondary controls are included as part of testing to account for background water quality related responses. In our study, monthly ambient surface water samples from the Sacramento-San Joaquin Delta, California, were collected from multiple locations in 2015, 2016, and 2017 as part of a regional monitoring program. These samples were characterized with short-term chronic toxicity testing and current use pesticide analyses. Toxicity tests included low electrical conductivity (EC) controls when ambient samples had specific conductance below 100 uS/cm. *C. dubia* reproduction in the lab culture water controls averaged 28.6 neonates/female while reproduction in the low-EC controls averaged 20.8. Reproduction in the low-EC controls was significantly lower from that in the standard culture water controls in 12 of the 22 tests, with low-EC effects observed in conductivities up to 127 uS/cm. Although there is a lack of guidance in use of secondary controls, USEPA (2000) describes the need to include a concurrent dilution control (i.e., secondary control) when the dilution water differs from the water used to culture the test organisms (i.e., primary control). The sample result should be compared to the secondary control result when the two controls responses are not significantly different from each other. In this light, it may be appropriate to evaluate the test organism response relative to the control with water quality most similar to the tested sample, depending on program objectives. However, the USEPA does not offer guidance on evaluating samples when there is a significant difference between the primary and secondary controls. This may indicate that the secondary control responses were outside of the test organism tolerance, that acclimation of the test organisms may be necessary or a different species may be more appropriate for use in these low conductivity ranges, or that project managers may wish to reevaluate test objectives. This presentation will share data and potential test interpretations that can be made, and will provide suggestion on how to interpret tests when using dual controls for ambient water testing programs.

**587 Method development for conducting effluent tests with the mayfly Neocloeon triangulifer**

*D.J. Soucek, Illinois Natural History Survey; A. Dickinson, Illinois Natural History Survey / Ecology; T.J. Norberg-King, USEPA / NHEERL / Mid-Continent Ecology Division*

Currently, USEPA relies on three freshwater species for short-term toxicity testing in a variety of programs and all tests are 8-d in duration or less. These methods are published in USEPA's Short-Term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to Freshwater Organisms. The methods use a fish, a cladoceran, and an alga, but to date, there have been no EPA-approved methods to use sensitive invertebrates like mayflies, which are among the most sensitive species tested with metals and major ions, to support NPDES permit decision-making (i.e., via incorporation of whole effluent toxicity (WET) tests). Methods for conducting acute 4-day and full-life chronic (~25-30-d) toxicity tests with the mayfly (*Neocloeon triangulifer*) have been published, but there is a need to extend the methodology so that it is applicable for testing effluents and receiving waters in a short-term exposure (e.g., 7 or 10 d). Our studies involved identifying an optimal starting age, test duration, and sub-lethal endpoint for WET testing. Others have compared sensitivity of this species at 0, 3, and 5 days-old, and we sought to further investigate this question with independent experiments comparing 0 and 7 day old organisms in 7 and 14-d tests. We also developed a length versus dry weight relationship for this species with the idea that while dry weight is a more sensitive endpoint than length, length is much easier to consistently and accurately measure with young instars of this species. The other objective of this study was to investigate and further refine various aspects of diatom culture technique on food quality and therefore mayfly growth. Optimizing diet for these organisms may be critical for achieving consistently high growth rates with low intra-treatment variability. Results of the study will provide further data needed to guide the development of a whole effluent toxicity test method for mayflies. *This abstract does not necessarily represent the position or policy of the USEPA.*

**588 Method Development for Conducting Short-Term Effluent Tests with Freshwater Mussel (Fatmucket, Lampsilis siliquoidea)**

*N. Wang, J.L. Kunz, J.A. Steevens, USGS / Columbia Environmental Research Center; T.J. Norberg-King, USEPA / NHEERL / Mid-Continent Ecology Division; E. Hammer, USEPA; C. Bauer, USEPA / Water Quality Branch, Chicago; C. Barnhart, Missouri State University / Biology*

Short-term (6-8 d) freshwater toxicity test methods have been promulgated by the USEPA for estimating chronic toxicity of effluent and receiving water. These methods include a fish (*Pimephales promelas)*, a cladoceran (*Ceriodaphnia dubia)*, and a green alga (*Raphidocelis subcapitata*). Recent studies have demonstrated that a unionid mussel (fatmucket, *Lampsilis siliquoidea*) is one of the more sensitive species for ammonia, some metals, and major ion salts. Therefore, use of mussels as an additional species holds promise for effluent toxicity assessments. The objective of this study was to develop standard effluent test methods with fatmucket by, initially, determining optimum feeding rates and starting ages of juvenile mussels (~1-, 2-, and 3-wk old) in a 7- and 10-d feeding study; afterwards, assessing the sensitivity of the three ages of mussels in 7- and 10-d NaCl toxicity tests; and finally evaluating the performance and variability in the mussel methods through an interlaboratory study. For the feeding study, an algal mixture (~510 nl cell volume/mL) was prepared by mixing a commercially available algal concentrate and shellfish diet in test water (diluted well water at a hardness of 100 mg/L $CaCO_3$). The mussels were fed at four rates in the feeding study: adding 1, 2, or 3 mL of algal mixture twice daily or 4 mL once daily into each replicate chamber containing 200 mL of water. Mean survival was ≥93% in all feeding treatments except for the 4 mL fed once a day to 1-wk-old mussels (78%). The increase of mussel shell length ranged from 24 to 52% at test day 7 and from 28 to 60% at test day 10 among the four feeding treatments. The best growths (length) were observed at the feeding rate of 2 mL twice daily in treatments started with 1- to 2-wk-old mussels (~0.3 to 0.4 mm length), and at a higher feeding rate of 3 mL 2 times daily for 3-wk-old mussels (~0.5 mm length). The optimum feeding rates were used in the 7- and 10-d NaCl toxicity tests started with the 1-, 2-, or 3-wk-old mussels. For both test durations, the growth was consistently more sensitive than survival, and the sensitivity to NaCl was essentially the same among the three ages of mussels. An interlaboratory study has been organized and will be performed in thirteen volunteer laboratories from the United States and Canada, using 1-wk-old fatmucket in a 7-d NaCl exposure. *Disclaimer: This presentation does not necessarily reflect the views or the policies of the U.S. Environmental Protection Agency*

## Chemical Prioritization Using 21st Century Science: Considerations for New Approach Methodologies

**589 New Approach Methodologies--Fools Gold or the Mother Lode?**

*P.C. DeLeo, Integral Consulting Inc.; S. Hartigan, American Chemistry Council / Regulatory and Technical Affairs*

New approach methodologies (NAMs) offer a more rapid and inexpensive means for development of relevant information to understand potential environmental risks of chemicals in products. The United States Environmental Protection Agency (EPA) in its recent Draft Strategic Plan to Promote the Development and Implementation of Alternative Test Methods expanded the concept of NAMs to include tools for chemical characterization; hazard identification and characterization; dosimetry and in vitro-in vivo extrapolation (IVIVE); and characterization of exposures to humans and the environment. EPA's vision of NAMs may be driven by the fact that its regulatory programs for chemicals in commerce are evolving due to recent reform of the Toxic Substances Control Act (TSCA), which requires EPA to prioritize and evaluate the risks of the thousands of chemicals on the TSCA Inventory. However, the need for expanded capacity and for more efficient and effective tools for prioritization and risk assessment of chemicals is not unique to the United States; the European Chemical Agency and the Canadian government also have significant programs applying NAMs. We provide an industry perspective regarding opportunities to reduce the use of vertebrate animals in toxicity testing and deliver greater value to industry, regulators, and stakeholders through chemical prioritization and ecological risk assessments that can be developed faster, at reduced cost, and with reduced uncertainty. In addition, we explore NAMs that go beyond replacing vertebrate animal testing, such as those that utilize in silico tools (e.g., QSPR, QSAR), existing data through read-across techniques, and existing high-throughput in vitro assay data incorporated into weight-of-evidence screening, prioritization, and assessment. Emphasis is placed on the processes needed to assure regulatory acceptance of NAM data, including critical engagement of industry, regulators, and other key stakeholders.

**590 Evaluation of Three Interventions to Improve Design and Safety of Industrial Chemicals**

*D. Faulkner, University of California, Berkeley; M. Tagmount, University of Florida / Center for Environmental and Human Toxicology; V. De La Rosa, Silent Spring Institute; F. Lambert, University of Florida / Center for Environmental and Human Toxicology; L. Rubin Shen, University of California, Berkeley / College of Chemistry; D. Johnson, University of California, Berkeley / Nutritional Science and Toxicology; C. Vulpe, University of Florida / Department of Physiological Science and the Center for Environmental and Human Toxicology*

Despite their ubiquity in modern life, industrial chemicals are poorly regulated in the United States. Statutory law defines industrial chemicals as chemicals that are not foods, drugs, cosmetics, nor pesticides, but may be used in consumer products, and this distinction places them under the purview of the Toxic Substances Control Act (TSCA). The Frank R. Lautenberg Chemical Safety for the 21st Century Act addresses many but not all of TSCA's failings, and rightfully emphasizes the development and adoption of high throughput screens, in vitro, and alternative assays to improve the process for registering new chemicals and to address the tens of thousands of untested chemicals currently in the TSCA inventory. As the discipline of toxicology gradually shifts from its' history as a reactive science (responding to problems after they've occurred) to a proactive science (attempting to predict and circumvent dangers to human and environmental health), two things become clear: 1.) traditional low throughput toxicological testing methodologies are inadequate to address both the volume of chemicals of interest and the pace of research; and 2.) the modern industrial chemical ecosystem is complex and no single testing solution will be appropriate for all the actors that populate that ecosystem. To address these challenges, three interventions were investigated, each of which targets a different population within the industrial chemical ecosystem. The first intervention was a suite of computational toxicology methods targeted towards chemists in the initial phases of chemical design and development. The second intervention was an alternative assay, the yeast functional toxicogenomic assay, permits industrial or government labs to rapidly evaluate differences in cytotoxic mechanism between different chemicals – even if they are structurally very similar. The third intervention explored was a method for enhancing the metabolic capacity of cell lines currently used by regulators for high throughput cytotoxicity testing. These interventions individually are not necessarily appropriate for all actors across the US industrial chemicals ecosystem, but as bespoke solutions they may be quite useful, and, it is hoped, support a larger exploration of where and how similar efforts may be spent most effectively to reduce industrial chemical hazard.

**591 Can Alternative Toxicity Testing Methods Be More Efficient Than Traditional Methods?**

*K. Mittal, McGill University / Dept of Natural Resource Sciences; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; J. Head, McGill University / Natural Resource Sciences; G. Hickey, McGill University – Macdonald Campus / Natural Resource Sciences; S. Maguire, McGill University / Desautels Faculty of Management; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre; J. Xia, McGill University; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences*

Chemical contamination is considered to be one of the planet's greatest threats with numerous chemicals lacking basic toxicity information. Traditional animal-based toxicity testing involving characterizing apical measures (e.g., survival, growth, development) that has been the mainstay since the 1920s, is in the midst of transforming to an approach founded on a diverse range of new approach methods (NAMs). Such alternative testing methods are said to be faster, cheaper, and use fewer animals, however, there is little empirical evidence to support these notions. The objectives of this research were to A) examine the evolving field of environmental toxicity testing by outlining key events, challenges, and opportunities, B) synthesize available information on costs associated with money, time, and number of animals used, and C) present select case studies highlighting the potential benefits of using alternative approaches. Deliberate bibliometric searches were carried out for papers and reports detailing various costs associated with toxicity testing. We observed that events such as seminal publications on toxicity testing in the 21$^{st}$ century (TT21C) and the increasingly global threat of chemical contamination, and international legislations on chemical testing have highlighted the need for a paradigm shift in toxicity testing. Current challenges are manifold: there are 20,000 to 100,000 chemicals registered in commerce worldwide; concomitantly, there is an urgent need for faster and more resource efficient methods that can provide the type of data usable for regulatory purposes. Technological advancements including high throughput sequencing, toxicogenomics, bioinformatics, and adoption of the adverse outcome pathway framework along with large-scale efforts such as ToxCast can help realize the vision of TT21C in ecotoxicology by prioritizing 3-15% of chemicals that are estimated to need further animal testing. Comparisons between various toxicity tests indicate that whole animal tests tend to be more expensive than alternatives (median cost: \$118,000 vs \$2,500), are slower (20 weeks vs 3 weeks), and use more animals (130 vs 20). While the inherent experimental differences between traditional and alternative methods make it difficult to directly compare costs, select case studies such as the use of custom designed qPCR arrays and the endocrine disruptor screening program demonstrate that there is scope for the implementation of alternative methods.

**592 In silico computational transcriptomics reveals novel endocrine disruptors in Largemouth bass (Micropterus salmoides)**

*D. Basili, University of Liverpool / Institute of Integrative Biology; J. Zhang, University of Florida; J. Herbert, University of Liverpool / Institute of Integrative Biology; K.J. Kroll, N.D. Denslow, C.J. Martyniuk, University of Florida / Physiological Sciences; F. Falciani, University of Liverpool; P. Antczak, University of Liverpool / Institute of Integrative Biology*

In recent years, decreases in fish populations have been attributed, in part, to the effect of environmental chemicals on ovarian development. To understand the underlying molecular events, we developed a dynamic model of ovary development linking gene transcription to key physiological endpoints, such as gonadosomatic index (GSI), plasma levels of estradiol (E2) and vitellogenin (VTG), in largemouth bass (LMB) (*Micropterus salmoides*). By mapping the responses of a transcriptome from LMB collected from a polluted site, we were then able to identify modules (clusters of genes), which are perturbed at different stages of ovarian development. A sub-network was identified that closely linked

gene expression and physiological endpoints and by interrogating the Comparative Toxicogenomic Database (CTD), Quercetin and Tretinoin (ATRA) were identified as two potential candidates that were associated to the observed molecular response in LMB ovary following reproductive disruption. Predictions were validated by investigation of reproductive associated transcripts using qPCR in ovary and in the liver of both male and female largemouth bass treated after a single injection of Quercetin and Tretinoin (10 and 100 µg/Kg). Both compounds were found to significantly alter the expression of some of these genes. This study demonstrates that by utilizing computational approaches and online knowledge bases to understand the underlying molecular response of organisms, it is possible to identify putative chemical candidates that may impact reproductive health. This approach is highly relevant for classifying chemicals prior to conducting risk assessments, and we propose that this is a viable approach for chemical prioritization, reducing animal numbers, and developing safer chemicals in the public domain.

**593 Incorporating Lifecycle Emission Information in Promoting Chemical Exposure Screening**

*L. Li, University of Toronto at Scarborough / Department of Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting / Department of Physical & Environmental Science/Department of Pharmacology and Toxicology; F. Wania, University of Toronto at Scarborough / Physical and Environmental Sciences*

While high-throughput human chemical exposure screening often relies on hazard indicators such as persistence and bioaccumulation potential, realistic human chemical exposure and potential health risks are also dependent on factors such as chemical use information and chemical-specific exposure pathways. Multimedia, multi-pathway exposure models are being used for chemical prioritization and screening, the parameterization of which requires chemical specific use and emission information (e.g., how is it emitted? how much?). This information, however, is often insufficient or missing for most chemicals in commerce. To address this issue, we propose integrating substance flow analysis, which is a powerful tool to derive chemical emissions throughout the chemical/product lifecycle, into high-throughput screening for human exposure potential. As an illustrative example, we combine a substance flow model (a simplified version of CiP-CAFE) with chemical fate and exposure models (RAIDAR and RAIDAR-ICE), to create a modeling continuum from the quantity produced or imported to human aggregate exposure. Our model requires inputs of basic properties of chemicals (e.g., partitioning coefficients, and degradation/biotransformation rates) and associated products (e.g., use categories, lifespans and material characteristics). These properties can either be retrieved from existing data resources or calculated by models, which enables the model's wide applicability to high-throughput screening of both existing and new substances. The model allows "forward" evaluation of human aggregate exposure to chemicals arising from their actual use, or "back" calculation of the critical production/import quantities of a chemical that would not cause an unacceptable level of risk (the latter depends on the availability of toxicological data). Overall, the approach shows promise in high-throughput exposure screening of the myriad of chemicals.

**594 Application of the RAIDAR Model to Aid Chemical Prioritization in Canada**

*J.A. Arnot, ARC Arnot Research & Consulting / Department of Physical & Environmental Science/Department of Pharmacology and Toxicology; J.M. Armitage, AES Armitage Environmental Sciences, Inc / Physical and Environmental Sciences; L. Toose, Liisa Toose Environmental Research; M.A. Bonnell, Environment and Climate Change Canada / Ecological Assessment Division*

A common approach used in regulatory programs to evaluate chemicals for their potential effects on the environment is to categorize chemicals using various criteria for Persistence, Bioaccumulation and Toxicity (PBT). Alternative methods screen and prioritize chemicals based on estimates of exposure and potential risk. In the US, recent amendments to the Toxic Substances Control Act (TSCA) have led the United States Environmental Protection Agency (USEPA) to consider new approach methodologies (NAM) in many aspects of TSCA implementation including prioritization. Much focus has been directed towards in vitro toxicity testing. As highlighted in the National Academy of Sciences, Engineering and Medicine report "Using 21st Century Science to Improve Risk-Related Evaluations" there is a need to develop and evaluate exposure models to compare against existing and emerging data streams of toxicity information to guide risk-based decision-making. The Risk Assessment IDentification And Ranking (RAIDAR) model combines chemical fate and transport at a regional scale with bioaccumulation in aquatic, terrestrial and agricultural food webs using toxicokinetic models. RAIDAR simulated external and internal exposures to a range of ecological receptors and humans are quantitatively compared to toxicity data expressed in terms of external (e.g., LC50, TTC, or eco-TTC) or internal (e.g., critical body residues) effect or no effect concentrations in RAIDAR calculated Risk Assessment Factors (RAFs). The latest version of RAIDAR includes methods to better simulate the fate, bioaccumulation and exposure for ionogenic organic chemicals (IOCs). We applied the model to approximately 10,000 organic chemicals on the Canadian Domestic Substances List using various methods for characterizing chemical toxicity (i.e., LC50s, critical body residues and chemical activity) in a risk-based prioritization exercise. The results of RAIDAR modeling will be integrated into version 2.0 of ECCC's Ecological Risk Classification (ERC) approach which is being developed as one approach to inform chemical priorities for post 2020 chemicals management in Canada. The RAFs span approximately 10 orders of magnitude. The greatest overall source of uncertainty in the RAF is the emission rate followed by biotransformation half-life estimation and toxicity information. The results of the RAIDAR calculated RAFs for chemical prioritization are compared against PBT categorization results.

**595 3D-Cultured Avian Cells for Chemical Screening: Metabolic and Gene Expression Profiles of the Chicken LMH Cell Line**

*T. Sharin, University of Ottawa; D. Crump, J. O'Brien, Environment and Climate Change Canada / National Wildlife Research Centre*

There has been an increased demand for in vitro toxicity testing in order to efficiently screen and prioritize the vast number of chemicals in the environment that require assessment. Primary cell culture approaches have been the most common in vitro model for toxicity testing and chemical screening in avian species. However, the preparation of primary cells is relatively time consuming and requires the use of many animals. The use of immortalized cell lines could eliminate these requirements. Furthermore, advances in 3D culturing techniques permit cells grown in vitro to have a more tissue-like metabolic and gene-expression response to external stressors. In this study we began to investigate if the immortalized chicken hepatocellular carcinoma cell line, LMH, could be a suitable alternative to primary chicken embryonic hepatocytes (CEH) when used in a well-established assay for chemical screening and prioritization. LMH cells were grown as two-dimensional (2D) monolayers (proliferating and confluent cells) and as three-dimensional (3D) spheroids. Cytochrome P450 (CYP1A4) activity and gene expression were compared between CEH and LMH grown in all three culture conditions following exposure to the dioxin-like compound 3,3',4,4',5-pentachlorobiphenyl (PCB126). CYP1A4 activity was measured using the EROD assay and changes in mRNA expression, associated with the aryl hydrocarbon receptor (AhR) pathway, were determined using a custom-designed PCR array. LMH cells only showed EROD induction when grown in 3D spheroids, although at a lower level than CEH. Similarly, the greatest numbers of AhR-related genes were induced in LMH 3D spheroids compared to proliferating and confluent cells. Overall, these results suggest that LMH cells grown as 3D spheroids have a metabolic and gene expression response that is comparable to CEH, and may make a suitable animal-free alternative for in vitro screening of chemicals.

**596 Pulling New Methodologies into Integrated Approaches to Testing and Assessment: A Chemical Industry Perspective**

*K.K. Coady, Y. Chai, The Dow Chemical Company / Toxicology and Environmental Research and Consulting; D. Wilson, The Dow Chemical Company; S. Marty, Dow Chemical Company / Toxicology and Environmental Research and Consulting*

Chemical companies employ early screening methodologies during chemical research and development to screen out chemicals that show signs of unwanted toxicological hazards or a poor environmental fate profile. These early screens include a combination of in silico tools and in vitro assays that are designed around key events or indicators linked to adverse outcomes or undesirable environmental fate parameters (*e.g.* PBT, endocrine disruption, sensitization). The results from early screens can be used to guide subsequent testing, including in vivo evaluations which are required, in many cases, for chemical registration in different geographies. In order to provide guidance on the conduct and interpretation of data from diverse sources (*e.g.* phys/chem parameters, in silico*,* in vitro*,* and in vivo data) integrated approaches to testing and assessment (IATA) have been developed for endpoints that are critical for evaluating safety for human health and the environment. Several IATAs that have been developed within the chemical industry will be presented, including those associated with endocrine activity, bioaccumulation, and ecotoxicity. The role of new approach methodologies in these IATAs will be emphasized, and data gaps, where they exist, will be noted. Several chemical case studies and their evaluations in relevant IATAs will be presented with associated learnings and recommendations for future improvements.

## Current-Use Pesticides: Exposure and Effects on Non-Target Organisms and Ecosystems – Part 1

**597 Exposure and effects of clothianidin residues in corn pollen: Honey bee colony simulation in a field setting**

*A. Schmolke, Waterborne Environmental, Inc. / College of Biological Sciences; F. Abi-Akar, Waterborne Environmental Inc; S. Hinarejos, Valent USA LLC*

As managed pollinator species, honey bees provide major pollination services to a wide variety of crops across the globe. At the same time, they are potentially vulnerable to the effects of systemic neonicotinoids because residues can occur in pollen and nectar collected by the bees. However, the assessment of potential effects of neonicotinoids on colonies in field studies is challenging because multiple environmental conditions interact with the colonies' health. Honey bee colony models such as BEEHAVE provide the opportunity to assess potential influx of residues into a colony via different routes, and their effects on bees in the hive can be dependent on their stage-dependent consumption rates and sensitivities. We extended BEEHAVE to represent exposure to clothianidin via residues in pollen from treated corn fields. Landscapes around the colonies were simulated using land cover data from sites across the Midwest of the United States. Simulated foragers collect pollen from flower resources across the landscape including corn pollen during the corn blooming period. Clothianidin residues are consumed by larvae and worker bees. Different residue levels in corn pollen were applied to assess impacts on honey bee colonies over a one-year cycle. Clothianidin effects on colony strength were only observed if unrealistically high residue levels in the pollen were simulated. The landscape composition significantly impacted the collection of pollen (residue exposure) from the corn fields, resulting in higher colony-level effects in landscapes with low proportions of semi-natural land. The case study with the mechanistic honey bee colony model presents a path to the application of such models in the context of pesticide risk assessment.

**598 Influence of flower resources and neonicotinoid exposure on bumble bee colony development and reproduction**

*M. Rundlöf, Lund University / Department of Biology; O. Lundin, Swedish University of Agricultural Sciences SLU / Department of Ecology; N. Williams, University of California Davis / Department of Entomology*

Bees in agricultural landscapes are affected by numerous stressors and a key limiting factor is lack of flower resources. Mass-flowering crops can mitigate this stress, but such nectar and pollen resources are often contaminated with pesticides that can negatively affect bee abundance and reproduction. Our understanding of how the interplay between flower resources and pesticide exposure affects bee colonies foraging in real landscapes is, however, limited. To explore this, we placed three bumble bee (*Bombus terrestris*) colonies in each of 18 landscapes of three types. Six landscapes were centered on conventionally managed red clover seed fields treated with the neonicotinoid thicaloprid (flower resources + pesticide exposure), 6 landscapes were centered on organically managed red clover seed fields (flower resources) and 6 landscapes lacked red clover seed fields within a 2 km radius (control landscapes). We confirm that bumble bees foraging in red clover seed fields treated with thiacloprid to control seed predating weevils were temporarily exposed to high levels of thiacloprid through pollen. However, the exposure level declined sharply over a two week period after spraying. Bumble bee colonies grew larger in landscapes with thiacloprid treated red clover seed fields, compared to colonies in landscapes without red clover seed fields. Colony weights did not differ between landscapes with thiacloprid treated red clover seed fields and landscapes with organically managed, non-pesticide treated red clover seed fields, indicating that the red clover provides important resources that support colony growth even when treated with thiacloprid. Production of new queens was positively related to peak colony weight. Although queen production did not differ significantly between the three landscape types, reproduction was numerically lowest next to treated clover fields after taking into account that these colonies grew the largest. We conclude that thiacloprid for pest control in red clover seed production appears to be of low potential risk to bumble bees, although further studies are needed to exclude possible negative impacts on bee reproduction. We suggest that addition of flower resources in agricultural landscapes can be an option to support pollinators even if they contain residues of pesticides.

**599 Assessing native bee abundance and species richness in imidacloprid-treated soybean fields and surrounding field-margins**

*A. Main, University of Missouri, Columbia / School of Natural Resources; L. Webb, USGS / University of Missouri / School of Natural Resources; K. Goyne, University of Missouri, Columbia / Soils Environmental and Atmospheric Sciences; D. Mengel, Missouri Department of Conservation*

Unlike honeybees, numerous wild bee species nest belowground and in close proximity to cultivated fields and flower foraging areas. Although agricultural field-margins can serve as important bee habitat, these areas may also accumulate neonicotinoid insecticides via environmental transport processes (e.g., runoff events and dust migration during planting). However, few field studies have evaluated neonicotinoid impacts on wild pollinator communities, including solitary, ground-nesting bees (e.g., sweat bees, longhorn bees). To assess effects of neonicotinoid exposure on native bee abundance and species richness, we sampled 30 soybean fields on five conservation areas in north-central Missouri from pre-seeding through harvest in 2017. Following baseline data collection in 2016, soybean fields were cultivated using one of three treatments: imidacloprid-treated fields ($n$=10); untreated fields ($n$=10); and previously treated (2016) to untreated fields ($n$=10). At each site, we collected field and field-margin soils, flower heads from wildflowers and soybean crops, and native pollinators every 28 days over five sampling periods (pre-seeding, post-seeding, growing, soybean flowering, and harvest). Neonicotinoid residues were detected in field soils during all sampling periods (frequency: pre-seeding, 7%; post-seeding, 33%; growing, 23%; soybean flowering, 53%; and, harvest, 33%). However, neonicotinoids were infrequently detected in margin soils (< 8% frequency, overall) with no residues detected in flowers from field-margins plants or soybean crops during the 2017 experimental year. Compared to untreated or previously treated fields, native bee richness was significantly less in neonicotinoid-treated fields ($\beta$ = -0.24 ± 0.10, $P$ = 0.05). Abundance of the more common genus *Melissodes,* which is composed of both generalist and specialist bees, was significantly less in fields with increasing soil concentrations of imidacloprid ($\beta$ = -1.33 ± 0.36, $P$ = < 0.001; marginal $R^2$ = 0.39). Here, we present our preliminary findings and discuss how this research improves our understanding of neonicotinoid seed-treatment use on non-target native pollinator communities within agroecosystems.

**600 Colony Level Impacts of Chronic Clothianidin Exposure via Spiked Pollen in Honey Bee Hives**

*A.W. Olmstead, Bayer CropScience / Environmental Toxicology and Risk Assessment; S. Bocksch, Eurofins Agroscience Services Ecotox GmbH / Ecotox Honeybees; M. Hill, Eurofins AgroScience Services Inc; J. Louque, Louque Agricultural Enterprises*

Clothianidin is a systemic insecticide that can be detected in the pollen and nectar of treated crops. In order to evaluate the chronic toxicity of this neonicotinoid to honey bee colonies via a pollen route of exposure, pollen patties were spiked with test material and provided to colonies over a six week period. Pollen traps were affixed to hives in order to minimize incoming foraged pollen and maximize the consumption of the treated diet. Two separate pilot studies were conducted in 2017 with measured treatment concentrations of 82, 372 and 1460 ppb in one study and 127, 339 and 991 ppb in the second study. All control and treatment hives were replicated 8 times for both studies. In the high treatments in both studies the presence of dead bees in front of hives indicated elevated mortality at these concentrations. Three weeks into the exposure period, numbers of adult bees were significantly lower in the high treatments compared to the controls. Other colony assessment parameters (e.g., honey, brood) were not significant at this time point; however, by the end of the six week exposure period all colony condition endpoints were significantly lower in the high treatment colonies. These differences persisted until the end of the studies which was two months after the end of the exposure period. Lower pollen patty consumption was observed at the 372 ppb treatment, but no other significant differences from the control were observed at this level. Residue sampling from bee bread and uncapped nectar in the hives indicated minimal movement of clothianidin from the treated pollen patties into the hive food stores. While some clothianidin detections occurred, none were above the limit of quantitation (1 ppb for uncapped nectar, 2 ppb for bee bread). A definitive, GLP colony feeding study with spiked pollen patties will run from May 2018 to April 2019 with nominal test levels of 100, 200, 400, 700, and 1000 ppb. Data generated in the first half of this third study will be presented alongside results of the first two studies to evaluate the consistency of the study conclusions.

**601 Imidacloprid Monitoring in Urban Surface Waters of California, USA**

*M. Ensminger, R. Budd, Cal EPA / Dept. of Pesticide Regulation; D. Wang, Cal EPA; N. Singhasemanon, Cal EPA / Pesticide Regulation*

Imidacloprid is a neonicotinoid insecticide used to control fleas, wood infesting pests such as termites and ants, and agricultural insect pests. Although neonicotinoid insecticides have come under scrutiny as a contributing cause of pollinator bee colony collapses, they also are quite toxic to sensitive aquatic organisms. Imidacloprid has been frequently detected in agricultural runoff; however, less is known about its environmental fate in urban landscapes. To address this, in 2010 the California Department of Pesticide Regulation initiated statewide imidacloprid monitoring at two main urban site types: storm drain outfalls and receiving waters. In addition, two small residential-neighborhood constructed wetlands were monitored. Imidacloprid was detected in over half (58%) of the 615 samples collected through March 2018. Imidacloprid detections were more frequent, with higher concentrations: 1) in Southern California than in Northern California; 2) at storm drain outfalls than at receiving water sites, and 3) during first flush rain events than during subsequent winter storms or non-rain (dry season) periods. However, non-storm mass loading contributed to a significant percentage of annual mass loading. This work shows that imidacloprid is a common contaminant in urban surface water, especially in Southern California, where imidacloprid is frequently detected at potentially toxic concentrations to sensitive aquatic organisms (i.e., above USEPA aquatic life benchmarks). Constructed wetlands in residential neighborhoods were ineffective in mitigating imidacloprid runoff. Therefore, alternative mitigation practices will be needed to reduce imidacloprid contamination in urban surface waters.

**602 Effects of environmentally realistic concentrations of neonicotinoid insecticides on aquatic invertebrates at population and community-levels**

*C. Duchet, Washington State University / Department of Evolutionary & Environmental Biology; C. Mackenzie, Washington State University Puyallup; C. Mitchell, Washington State University / School of the Environment; A. Kraft, Washington State University Puyallup; J.D. Stark, Washington State University / Dept of Entomology*

Neonicotinoid insecticides represent 24 % of the global market, and their use is increasing globally. Among them, clothianidin, imidacloprid, and thiamethoxam are widely used systemic insecticides, but are also used for lawn and garden care, and pest control. Residential usage has been linked to the occurrence of toxic level of pesticides in urban water bodies. Neonicotinoids are highly soluble in water and persistent in soil, and even though they are not intended for use in water bodies, they may enter in the aquatic compartment via spray drift, runoff or leaching, and contribute to downstream aquatic toxicity. Neonicotinoids interfere with the insect nervous system, and exhibit very high selectivity for insect nicotinic acetylcholine receptors. Although insects appear to be the most sensitive, some studies have shown effects of neonicotinoids on the crustaceans *Ceriodaphnia dubia* and *Daphnia magna*. However, most of the studies focus on single-insecticide exposure and very little is known concerning the impact of neonicotinoid mixtures on the environment and their combined toxicity on invertebrate community. As a first step, we tested the effect of a mixture of imidacloprid, clothianidin and thiamethoxam at concentrations measured in the environment, on *C. dubia*, at the population level and under controlled conditions. Population growth rate $\lambda$ was lower under exposure to the neonicotinoid mixture than in controls. Simulations performed using demographic stochasticity showed a higher risk to population extinction on mixture-exposed organisms (minimum abundance = 325, extinction risk = 0.07) in comparison to control (minimum abundance = 1208, extinction risk = none) and the mixture-exposed population never reached the carrying capacity (K = 500,000 individuals). Since neonicotinoid contamination is likely to induce a top-down trophic cascade in a community dominated by invertebrate predators, we then ran an outdoor mesocosm experiment to test the effect of the neonicotinoid mixture on an aquatic invertebrate community and to explore community-level effects. The community was sampled before the insecticide application and throughout the month following the treatment. Results will be discussed during the presentation.

**603 A field study assessing direct application of neonicotinoid seed treatment in wetlands: Implications for aquatic invertebrate communities**

*K. Kuechle, University of Missouri- Columbia / School of Natural Resources; L. Webb, USGS / University of Missouri / School of Natural Resources; D. Mengel, Missouri Department of Conservation; A. Main, University of Missouri, Columbia / School of Natural Resources; D.E. Tillitt, USGS / Columbia Environmental Research Center*

Neonicotinoid insecticides (NI) are commonly used as seed-treatments on major agricultural row crops (e.g., corn). Indeed, neonicotinoid treated agricultural crops are often planted directly in flood-plain wetlands managed for wildlife. Numerous studies have documented impacts of neonicotinoids to aquatic invertebrates in laboratory and mesocosm settings; however, less is known about impacts of neonicotinoids in field settings. We investigated invertebrate community response to planting of neonicotinoid-treated seed in managed wetland ecosystems. In 2016, we sampled water, sediment, and aquatic invertebrates from 22 paired wetlands on nine conservation areas during spring (pre-wetland draw-down) and fall (post-wetland flood-up) followed by a third sampling period (spring 2017, one year post-treatment). During summer, portions of sampled wetlands were planted with either untreated corn (control) or neonicotinoid-treated corn (thiamethoxam). Water quality parameters and concentrations of pesticides were used to evaluate effects of treatment on aquatic macroinvertebrate diversity and abundance using a series of generalized linear mixed effects models. Water and sediment concentrations of the six most common neonicotinoids were used to calculate overall NI toxicity equivalents (NI-EQs) based on an additive model of NI toxic equivalency factors (NI-TEFs: Cavallaro et al. 2017). Total mean NI-EQs for sediment (0.60 µg/Kg) were an order of magnitude greater than water (0.02 µg/L). Sediment neonicotinoid NI-EQs were greater in treated than untreated wetlands, both post-treatment (1.13 treated, 0.35 untreated, $p < 0.001$) and in spring 2017 (1.02, 0.28, $p < 0.001$). Water NI-EQs displayed similar results post-treatment (0.022 treated, 0.021 untreated, $p = 0.005$) and spring 2017 (0.014, 0.007, $p < 0.001$). Preliminary results indicate an overall decrease in aquatic invertebrate diversity and abundance with increasing concentrations of neonicotinoids in wetland water and sediment. Additionally, treated wetlands were observed to have lower invertebrate diversity and abundance compared to untreated wetlands post-treatment, but a recovery in abundance and diversity followed in spring 2017. Our results have implications for aquatic invertebrates as well as wetland-dependant species (e.g., waterfowl) as neonicotinoids concentrations, although below regulatory limits, are impacting these wetland ecosystems.

### 604 Invasive cane toads: Good for something? Developmental assays reveal safety concerns of the common rice herbicide, butachlor

*M. Shuman-Goodier, Northern Arizona University / Department of Biological Sciences; G.R. Singleton, International Rice Research Institute; S. Hines, Northern Arizona University; C. Propper, Northern Arizona University / Biological Sciences*

The intensification of rice agriculture and the corresponding increase in pesticide use poses a threat to biodiversity and human health. Amphibian species represent valuable indicators within rice ecosystems because they utilize them as habitat in the absence of natural wetlands, and pesticide applications often coincide with reproductive and developmental cycles. We conducted an experiment with wild cane toad (*Rhinella marina*) tadpoles at the International Rice Research Institute (IRRI) in the Philippines to 1) test whether environmentally relevant exposure to butachlor, an acetanilide herbicide used extensively in rice fields throughout Southeast Asia, affects development, behavior, thyroid physiology, and gene expression, and, 2) determine which developmental stages are most vulnerable to exposure, and 3) test the degree to which tadpoles are able to acclimatize to sub-lethal exposure. Our analysis revealed that *R. marina* exposed to butachlor developed slower, were less active, and weighed less, and that some concentrations affected the development of the thyroid gland: exposed individuals had fewer thyroid follicles and smaller thyrocyte cells. Furthermore, we found that *R. marina* eggs were more sensitive to exposure than tadpoles, and we observed compelling evidence of acclimatization: animals exposed to butachlor early in life performed better than naïve animals during a second exposure. Our findings support recent work indicating that butachlor causes thyroid endocrine disruption in vertebrates, and suggest that realistic exposure in rice fields presents a concern for wildlife populations and human health. Furthermore, because *R. marina* is a widespread invasive species and abundant within rice fields in the Philippines, we suggest using it as an indicator there, and in other tropical countries where it is native or has been introduced, to assess consequences of pesticide exposure.

## Adverse Effects of Chemicals on the Microbiome

### 605 Spatial and Temporal Shifts in Sediment Bacterial Community Composition Affected by Acidic Rock Drainage in the Animas River Watershed

*K. Thompson, Texas Tech University / Environmental Toxicology; J.E. Wilkinson, Harvard TH Chan School of Public Health / Department of Biostatistics; C. Phillips, Texas Tech University / Department of Biology; E. Rees, Texas Tech University / High Performance Computing Center; E.M. Peterson, P.N. Smith, G.D. Mayer, Texas Tech University / Department of Environmental Toxicology*

Acidic rock drainage (ARD) is a major source of metal pollution in aquatic ecosystems and is often associated with active and abandoned mines and mining-related activities. In Colorado alone, 230 hard-rock mines are known to release significant amounts of ARD. The Bonita Peak Superfund Site consists of 48 historic mining-related sources of ARD in southwestern Colorado which have heavily impacted the Animas River watershed for decades. Continual releases of ARD from the 48 sites compounded with natural weathering leaves several creeks on the headwaters of the Animas River with low pH and high concentrations of several toxic metals. As the metals flow downstream, they are sequestered in organic matter and settle in the sediment, creating a concentration gradient along the Animas River. Additionally, several 'blowout' events have been recorded, the latest on August 5, 2015, furthering the contamination of this watershed. Samples were collected in February 2015 and 2018. Thus, both temporal and spatial changes in bacterial communities downstream of ARD inputs in the watershed were examined. Further, given the timing of samples, we were able to compare the watershed after a blowout event to a watershed impacted by chronic, low-level releases of ARD. Closer to the Superfund site, chemotrophic extremophilic bacterial genera were identified. Specifically, we observed a high abundance of the genus *Gallionella* in our highly ARD polluted samples. Additionally, several other identified genera are thought to aid in the natural remediation of ARD. These genera may be suitable biomarkers of ARD contamination, or metal contamination from natural weathering, and could influence the remediation processes in these areas. Further down the concentration gradient, sediment microbiomes return to community structures more similar to those from non-impacted watersheds which are dominated by *Cyanobacterium, Rhodoferax,* and *Flavobacterium*.

### 606 The effect of nickel-contaminated sediments on the coral microbiome

*F. Gissi, CSIRO Oceans and Atmosphere; M.L. Gillmore, J. Stauber, CSIRO Land and Water; A.J. Reichelt-Brushett, Southern Cross University; L.A. Golding, CSIRO Land and Water; A. Chariton, Macquarie University / Molecular Ecology and Toxicology; P. Greenfield, CSIRO Digital Productivity; C. Humphrey, A. Severati, National Sea Simulator; D.F. Jolley, University of Wollongong / School of Chemistry*

The mining and production of nickel has recently intensified in the Asia-Pacific region. As a consequence, large quantities of particulate-bound nickel will be transported to the coast as land run-off, potentially placing marine ecosystems, including coral reefs, at risk of adverse effects related to increased nickel and suspended sediment exposure. Coral reefs throughout Asia-Pacific are facing enormous threats of decline due to anthropogenic climate change, physical destruction, overfishing, pollution and sedimentation. These threats are exacerbated by the limited information on the impact of mining activities on coral reefs and tropical marine biota. This study used experimental facilities at the National Sea Simulator, Townsville, Australia to investigate the response of the common branching coral, *Acropora muricata*, to nickel-contaminated suspended sediments. To separate the physical effects from the sediment and the chemical effects from nickel exposure, simultaneously treatments were performed which included dissolved nickel (seawater only), clean sediments, and nickel-contaminated sediments. The experimental design consisted of 9 treatments: nickel in seawater-only, clean sediments (~ 4mg Ni/kg), laboratory-spiked nickel sediments (~ 6000 mg Ni/kg), and a field-collected nickel-contaminated sediment (~ 240 mg Ni/kg). All sediments were tested at low and high suspended sediment concentrations (5 and 30 mg/L TSS). The biological effects observed included bleaching, *Symbiodinium sp.* density changes, metal accumulation and assessment of the microbiota community structure (using DNA metabarcoding). Coral fragments (4-10 cm) were acclimated to laboratory conditions for ~ 2 months and then exposed to flow-through treatment conditions for 7 days. Samples were taken on days 0, 4 and 7 to measure coral health and to preserve tissues for DNA extraction. After 7 days the exposure was ceased and the corals were allowed to recover in filtered natural seawater for a further 7 days, after which all parameters were measured again. We found that low concentrations of sediment-bound nickel (≤ 240 mg/kg) did not negatively impact coral health but high sediment-bound nickel concentrations in combination with a dissolved nickel exposure induced significant negative effects to coral health. The effects of nickel-contaminated sediments on the coral microbiome will also be discussed.

**607 Life-stage, and species-specific effects of dietary methylmercury exposure**

*K.N. Bridges, State of Alaska Division of Public Health / Environmental Public Health; Y. Zhang, University of North Texas Health Science Center; T. Curran, University of North Texas / Biology; J.T. Magnuson, University of California, Riverside / Environmental Sciences; K. Durrer, M. Allen, University of North Texas Health Science Center; B.J. Venables, A.P. Roberts, University of North Texas / Advanced Environmental Research Institut*

Mercury is a globally distributed contaminant, which is found even in remote aquatic ecosystems as a result of atmospheric deposition. Methylmercury, resulting from microbial transformation of inorganic mercury, bioaccumulates and biomagnifies in biota, resulting in potentially toxic body burdens in long-lived organisms at the top of aquatic food webs. Methylmercury can be actively transferred from mother to offspring, with the potential to cause severe, irreversible effects on developing organisms. Here, we describe the developmental effects of exposure to maternally-transferred dietary MeHg on a model fish species *(Pimephales promelas)*. Exposure to environmentally relevant concentrations of MeHg during development led to alterations in the dopaminergic system, metabolome, gene expression, behavior, hatch time, size, and embryo-larval survival. Similarly, effects on the dopaminergic system in specific regions of the adult *P. promelas* brain were observed after a 30-day dietary exposure. Recently, a functional link between gut microbiota and dopamine production in teleosts has been established. Therefore, we characterized MeHg-mediated changes to the gut microbiome composition in *P. promelas* adults. Because the dopaminergic system is highly conserved among taxa, we sought to confirm the altered dopamine concentrations in *P. promelas* brainin a higher vertebrate species. Metabolomics was performed on the mid-brains of male mice *(Mus musculus CD-1)*exposed to similar concentrations of dietary MeHg for 30-days. Changes in dopamine concentrations of the teleost brain were mirrored in the mid-brains of male mice, and several other significant changes to the mouse mid-brain metabolome were detected. Collectively, these results suggest current environmental exposure scenarios to MeHg are sufficient to induce a number of molecular-level changes that are associated with costs to whole organism fitness, with consequences for multiple life stages, and species. Due to the similar changes detected in mice, there is increasing evidence to suggest teleosts as a surrogate model species for studies assessing effects of MeHg on highly conserved systems.

**608 Shifts of microbiota of fish guts following exposure to dietary benzo[a]pyrene**

*A. DeBofsky, Y. Xie, University of Saskatchewan / Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences and Toxicology Centre*

Microbiota of animal guts have been described as an additional host ‘organ’ with well-established beneficial roles. However, little is known about the impact of a chemical exposure on both structure and function of gut microbiota of fishes. In order to determine the structural and functional shifts of gut microbiota of fathead minnows (*Pimephales promelas*) to chemical toxicants, juvenile fathead minnows were exposed to benzo[*a*]pyrene (BaP), a model compound simulating the effects of oil spills, at concentrations of 1, 10, 100, or 1000 µg/g, in addition to a vehicle control, for two weeks. Comparisons between multiple responses of gut microbiota, intestine, liver, and lymphocytes allow for discovery of an early warning response within exposed organisms. Overall and active compositions of gut microbiota will be characterized by use of DNA- and RNA-based 16s rRNA gene metagenetics, respectively. Expression levels of bacterial genes related with BaP degradation will be determined by RT-qPCR as well. Changes of several key genes related to BaP-exposure and immunotoxicity in gene transcript level will be determined by use of RT-qPCR with RNA isolated from intestines and livers from the hosts. Flow cytometry was used to determine shifts in lymphocyte proportions resulting from exposure. This research will provide preliminary information about the impact a controlled exposure may have on the interplay between host and bacteria, a lesser-understood component of environmental toxicity.

**609 A Comparative Analysis of Gill and Gut Microbiomes Across Fish Species Exposed to Oil, a Pathogen, or Both**

*M.L. Rodgers, R.J. Griffitt, University of Southern Mississippi / Coastal Sciences*

The microbiome is a complex assemblage of microorganisms that play an important, but poorly understood, role in mediating organism:environment interactions. Due to the complexity of the microbial assemblage, we are only beginning to understand how alterations to the microbiome may affect the host organism and its response to the exterior environment. Some research examining how the microbiome of fish exposed to xenobiotics is altered by that exposure has been done, but relatively little is known about how consistent or conserved induced alterations are. In order to understand how the microbiome varies across fish species with exposure to oil, exposure to a pathogen, and both simultaneously, juvenile red snapper (*Lutjanus campechanus*), Atlantic croaker (*Micropogonias undulatus*), red drum (*Sciaenops ocellatus*), and Southern flounder (*Paralichthys lethostigma*) were utilized. Fish were either exposed to high energy water accommodated fractions of oil (snapper, croaker, and drum), or oil mixed into sediment (flounder). All fish were exposed to oil for 7 days, then exposed to the known fish pathogen *Vibrio anguillarum* for one hour, followed by an additional 24 hours of oil exposure (8 days total). There were four experimental groups for each species: Control (no oil or pathogen exposure), Pathogen only (only exposed to *V. anguillarum* and not oil), Oil only (exposed to oil but not *V.* anguillarum), and Oil+Pathogen. Gill and gut tissues were harvested from all fish and microbiome analysis was performed for each sample. In Southern flounder, we found that in fish challenged with *V. anguillarum* in addition to oil, *V. anguillarum* accounted for nearly 40% of the gill microbiome and 20% of the gut microbiome, while all other groups (oil only, pathogen only, and control) had almost no representation from this species. In addition, flounder exposed to oil (regardless of whether or not they were also exposed to *V. anguillarum*) showed ~20% representation from *Alcanivorax* spp. in the gill microbiome, whereas this genus was not well-represented in control or pathogen-only groups. Finally, oil exposed versus non-oil exposed groups showed taxonomically distinct bacterial community assemblages, with gill and gut communities showing distinctions from one another.

**610 Effects of diet, taxonomy, and habitat on the gut microbiota of aquatic invertebrates**

*S. Kroetsch, University of New Brunswick Saint John / Biology and Canadian Rivers Institute; K.A. Kidd, McMaster University / Biology and Canadian Rivers Institute; S. Pavey, University of New Brunswick Saint John / Biology and Canadian Rivers Institute*

Most animals possess an internal and external community of bacterial microorganisms referred to as an organism's microbiome, of which the largest is present within the digestive tract. Whereas there has been considerable research linking human health to their microbiome, much less is known for aquatic organisms including macroinvertebrates. Before one can assess the effects of anthropogenic stressors on the microbiome, it is critical to develop an understanding of whether feeding habits and habitat affect the presence of gut bacteria. The current study assessed whether functional feeding groups, taxonomy or aquatic habitat characteristics impacted the gut microbiota of aquatic invertebrates in the Saint John River, New Brunswick, Canada. Sampling of macroinvertebrates from macrophytes, sediments and rocky habitats was conducted at several sites in October 2016 and in August 2017, and included Amphipoda, Trichoptera, Diptera, Ephemetoptera and Heterobranchia representing primary consumers through predators. Aquatic invertebrates were identified to the species level using the cytochrome c oxidase subunit I (*COI*) barcode. To assign taxonomic information to the bacterial sequences obtained from aquatic invertebrates, operational taxonomic units (OTUs) were generated using the V3-V4 hypervariable region of the *16S rRNA* genetic barcode at a 97% similarity threshold. The most abundant bacterial phyla across the gut microbiota of all aquatic invertebrates were Proteobacteria and Bacteroidetes, while the most abundant bacterial family was Enterobacteriaceae. It was found that the gut microbiota of aquatic invertebrates was related to invertebrate taxonomy – at the order and family levels – as well as their functional feeding group. For example, primary consumers had greater gut bacterial diversity, richness and evenness than predators. Additionally, water flow and substrate type also affected the gut microbiota. These findings will aid in establishing a baseline of natural variability and diversity upon which future hypotheses can be generated. This information is essential to determine before these techniques can be used to assess how or whether human activities affect aquatic organisms through their gut microbiome.

**611 Developmental estradiol exposure results in microbiota-dependent effects on locomotor activity in larval zebrafish**

*T.R. Catron, BASF Corporation; A. Swank, L. Wehmas, USEPA; D. Phelps, Oak Ridge Institute for Science Education at USEPA; J. McCord, Oak Ridge Institute for Science and Education / NERL; R. Singh, Oak Ridge Institute for Science Education at USEPA / Office of Research and Development / National Exposure Research Laboratory; J.R. Sobus, USEPA / Office of Research and Development / National Exposure Research Laboratory; S. Keely, N. Brinkman, C. Wood, USEPA; M. Strynar, USEPA / National Exposure Research Laboratory; T. Tal, USEPA*

Both natural and synthetic endocrine disrupting chemicals are known widespread environmental contaminants. During early vertebrate development, estrogen receptor signaling plays an important role in proper brain and nervous system development and function. Because host-associated microbial communities play important roles in nervous system development and can biotransform xenobiotics, we hypothesized that microbial colonization status may influence the neurobehavioral toxicity and chemical toxicokinetics of exogenous 17beta-estradiol (E2), a classic estrogen receptor agonist. To test this, conventionally colonized zebrafish were developmentally exposed to E2 in a semi-static system. At 10 days post-fertilization (dpf), mortality was assessed. 16S rRNA gene sequencing was used to evaluate potential shifts in microbial community composition and predicted metagenomic function following exposure to five non-teratogenic E2 concentrations (0.34–3.5 µM). Locomotor activity was assessed in colonized and axenic (microbe-free) zebrafish exposed to 0.4 or 1.2 µM E2 using a standard light/dark behavioral assay and zebrafish tissue was collected and analyzed using targeted and non-targeted chemistry techniques. Developmental exposure to E2 did not alter microbial composition or predicted function. Locomotor hypoactivity was observed in the light epoch in E2-exposed larvae colonized with microbes only; axenic larvae exposed to E2 exhibited a normal behavioral phenotype in the light. Targeted chemistry analysis revealed that axenic zebrafish contained three times more E2 than colonized zebrafish. Combined, these results suggest that host-associated microbiota bioactivate E2, resulting in an altered behavioral phenotype. These data demonstrate for the first time that chemical-induced neurobehavioral toxicity is dependent on the presence of microbiota and suggest that current hazard identification strategies have the potential to misestimate toxicological risk if chemical-microbiota interactions are not considered. *This abstract does not necessarily reflect EPA policy.*

**612 Host-microbiome alterations of fatty acid metabolism in *Danio rerio* following dietary phthalate exposure**

*A. Buerger, University of Florida / Environmental and Global Health; C.J. Martyniuk, University of Florida / Physiological Sciences; J. Bisesi, University of Florida / Environmental and Global Health*

Dysbiosis of the gut microbiome is associated with various health outcomes, such as colorectal cancer, anxiety, and obesity. The unprecedented increase in obesity rates globally is suspected to be exacerbated by exposure to environmental chemical contaminants, referred to as obesogens. Chemical exposure can alter gut microbial diversity, resulting in changes in microbial function that ultimately impact host function. Phthalates, a class of plasticizers commonly found in food containers, medical devices, and personal care products, are ubiquitous environmental chemical contaminants and suspected obesogens. We hypothesize that exposure to a common phthalate, diethyl-hexyl phthalate (DEHP), in addition to overfeeding, disrupts microbial diversity in the gut microbiome, leading to increases in microbial short chain fatty acid production, and altered lipid uptake and metabolism in the host gut tissue, ultimately leading to exacerbated obesity. *Danio rerio* (zebrafish) were randomly assigned to one of three groups: 1) Control 2) Overfed or 3) Overfed + DEHP. The exposure lasted for 60 days, and body mass index (BMI) was calculated at three time points over the course of the study. On the final day, zebrafish were euthanized and gut and fecal matter were excised for sequencing. Zebrafish showed elevated BMI in Overfed and Overfed + DEHP groups. 16s microbial sequencing of fecal matter revealed significant changes in β diversity, increases in Bacteriodetes, and decreases in Fusobacteria and Tenericutes in Overfed + DEHP zebrafish compared to Control and Overfed fish. In Overfed + DEHP compared to Overfed alone, PICRUSt analysis revealed significant changes in carbohydrate, galactose, inositol phosphate, and taurine and hypotaurine metabolisms. Changes in microbial function were paralleled by changes in host functions related to lipid metabolism and gut function, as revealed by RNAseq analysis and qPCR. Taken together, these data indicate that following DEHP exposure, there is disruption of microbial diversity and alterations in the abundance of communities associated with fatty acid production, as well as alterations in expression of corresponding genes related to fatty acid uptake and anabolism in the enterocytes of the host gut. These data suggest a role for DEHP in exacerbation of obesity following overfeeding through microbial dysbiosis in humans and aquatic organisms alike, which should be considered when regulating their release into the environment.

## Environmental Assessments for Human and Veterinary Pharmaceuticals – Evolving Regulations

**613 What's new at the US Food and Drug Administration? Part 1: The Center for Veterinary Medicine**

*H. Zahner, E.M. Silberhorn, US Food & Drug Administration / Center for Veterinary Medicine; J. Laurenson, R. Bloom, US Food & Drug Administration / Center for Drug Evaluation and Research*

This presentation, which is the first of two US Food and Drug Administration (FDA) presentations, will discuss current regulations, guidance, policy, and approaches used at the FDA's Center for Veterinary Medicine (CVM) to prospectively evaluate the potential for environmental impact of new animal drugs. Under the National Environmental Policy Act (NEPA), FDA is responsible for determining whether the agency's actions (e.g., approval of a new drug) will result in potential environmental impacts. NEPA provides tools, such as environmental assessments (EA) and categorical exclusions from the requirement to prepare an EA, for evaluating the environmental safety of agency actions. In addition, CVM has published a Guidance for Industry (GFI) with recommendations on how to conduct an EA that was developed and harmonized with regulatory agencies in the European Union and Japan, and has since been adopted by others. This guidance recommends a tiered approach to testing that includes an evaluation of the fate, transport, and effects of animal drugs in the environment, and recommends using a traditional risk quotient approach when assessing risk. However, CVM's GFI is not applicable to the evaluation of some new animal drugs. For example, the current GFI does not provide agency recommendations on how to estimate potential environmental concentrations in soil or water, or on how to evaluate an animal drug that has an unusual route of exposure (e.g., dietary), is known to be toxic at very low concentrations (e.g., endocrine active compounds, parasiticides), those that bioaccumulate in organisms, or those that persist in the environment. Examples of novel approaches used by the animal drug industry and CVM to address current issues will be presented. In addition, CVM's current and future scientific perspectives regarding the EAs for animal drugs will be discussed. During this presentation, a comparison between FDA's Center for Drug Evaluation and Research (CDER) and CVM's approaches to environmental risk assessment will also be provided.

**614 What's new at the US Food and Drug Administration? Part 2: The Center for Drug Evaluation and Research**

*R. Bloom, J. Laurenson, US Food & Drug Administration / Center for Drug Evaluation and Research; H. Zahner, E.M. Silberhorn, US Food & Drug Administration / Center for Veterinary Medicine; C. Pinto, US Food & Drug Administration / OCSPP / OSCP*

This presentation, which is the second of two from FDA, will address environmental assessment (EA) review activities at the FDA Center for Drug Evaluation and Research (CDER). CDER evaluates the safety, efficacy and quality of drugs for human use. The EA review at CDER primarily evaluates exposures, toxicity, and effects to environmental organisms due to the introduction of human drugs into waters and soils from patient use and drug disposal. To date, many high production volume drugs treating common diseases have been evaluated and many are now marketed in generic forms. A review of more current applications shows the nature and number of new drug applications and, in particular, new molecular entities (NMEs), changing significantly over the last decade. Currently, increasing numbers of accelerated approvals, breakthrough therapies, orphan drugs, personalized medicine, and targeted drugs are being submitted. Many of these drugs are produced at low levels and would not ordinarily be expected to elicit a toxic response in the environment; however, additional evaluations may be necessary for drugs with high toxicity and bioaccumulation potential. In the past, such low volume production drugs usually received routine exclusions from the requirement to submit full EA packages. Recently, FDA published a GFI (*Environmental Assessment: Questions and Answers Regarding Drugs With Estrogenic, Androgenic, or Thyroid Activity*) to explain that applications that claim a categorical exclusion when expected effluent concentrations arewww.fda.gov/drugdisposal). The Team also works closely with the EPA Office of Water to help prioritize research and publications on pharmaceuticals introduced into the environment. CDER recently published two articles: one on the risk assessment of ethinyl estradiol and a second paper that examines risks associated with the disposal of human pharmaceuticals. The Drug Disposal website and publications will be briefly discussed.

**615 Future challenges and regulatory improvements in the assessment of environmental risks from veterinary medicines – a European Perspective**

*J. Weeks, ERA*

This talk will focus on the current and future developments in the environmental risk assessment of veterinary medicine products (VMPs) from a European regulatory perspective. There is a need to continuously evolve and react to changing requirements to perform ever more sophisticated, quantitative or robust environmental risk assessments for veterinary medicine products. The centralised registration of new veterinary medicines within the EU, is the responsibility of the European Medicines Agency (EMA). EMA frequently has need of and takes advice from specialist working parties aligned to the specific provision or modification of regulatory guidelines or procedures. One such group, the Environmental Risk Assessment Working Party focuses on the improvement of the guidance to industry and other stakeholders on environmental risk assessment alongside the provision of reflection documents that aid understanding or address specific areas for clarification in regulatory procedures. The overview will highlight some of these recent developments, in improved regulatory advice for current or future procedures. It will summarily cover issues around assessing and limiting veterinary medicines in groundwater, the use of higher tier testing of dung fauna, the use of higher tier plant testing, improvements in PBT assessments, future plans around developing improved guidance for the assessment of risks from aquaculture medicines and VMPs and AMR in the environment. The talk will compare developments in improving the guidance on the assessment of VMPs in the environment at the EU level and seek comparison to similar challenges in North America by regulators and industry alike.

**616 An investigation of sexual maturity status as a confounding factor in screening assays for the detection of androgens and anti-estrogens**

*K. Roush, M.K. Sellin Jeffries, Texas Christian University / Department of Biology*

Given the prevalence and effects of some human and veterinary pharmaceuticals, regulatory bodies have placed there an increased emphasis on identifying endocrine disrupting compounds. Some pharmaceuticals have been identified as reproductive endocrine disrupting compounds (REDCs) capable of altering sexual development, reproductive success and behavior. As such, the goal of this project was to determine whether sexual maturity status, as assessed via the prominence of secondary sexual characteristics, in female fathead minnows (*Pimephales promelas*) influences their response to REDCs. Specifically, we sought to determine whether less sexually mature females differed from more sexually mature females in their responses to 17β-trenbolone (TB, a common veterinary pharmaceutical) and fadrozole hydrochloride (FZ, a human pharmaceutical). Adult female fathead minnows were sorted by the prominence of secondary sexual characteristics, exposed to TB or FZ for 7 days and sampled for the analysis of estrogen-responsive gene expression. Results showed that fish with highly prominent secondary sexual characteristics responded differently to REDCs than fish with less prominent secondary sexual characteristics indicating that sexual maturity status influences REDC exposure outcome. For example, a decrease in hepatic vitellogenin expression was detected in the more sexually mature females but was not detected in the less sexually mature females after exposure to TB; therefore, had less sexually mature females alone been utilized, the defeminizing effects of TB would not have been identified. These results indicate that sexual maturity status should be taken into consideration in the implementation of screening assays as failure to utilize fish of the “appropriate” maturity status can skew test results. Ultimately, by refining existing screening assays to ensure adequate detection of pharmaceutical REDCs, environmental assessments of these compounds will improve.

**617 Developing Guidance to Support the Canadian Regulatory Proposal for the Environmental Assessment of Medicinal Ingredients in Human/Veterinary Drugs**

*J. Chateauvert, Health Canada / Environmental Impact Initiative Division*

Currently, manufacturers and importers of medicinal ingredients in drugs must notify under the *New Substances Notification Regulations* (NSNR) under the *Canadian Environmental Protection Act, 1999* (CEPA) in order for the Government of Canada to conduct an environmental risk assessment. A new proposed Canadian regulatory framework is being developed specifically for medicinal ingredients in human and veterinary drugs regulated by the *Food and Drugs Act* (F&DA) to assess risks to the environment and to human health resulting from environmental exposure. This new regulatory framework has been designed to align with the drug approval process stipulated by the F&DA and its regulations, and to harmonize with international jurisdictions. The creation of a new regulatory framework has provided Health Canada regulators with an opportunity to investigate and address concerns and gaps within the current NSNR system with respect to medicinal ingredients in drugs so that data requirements can be designed with cutting edge technologies in mind. Specifically, this presentation will describe how new draft guidance that will accompany the proposed regulatory changes under the F&DA will address requirements that are specific to human cell-based therapies, as well as substances that are replicating versus non-replicating, while striving to create a streamlined drug approval process that is comparable internationally. The purpose will be to obtain feedback from international counterparts and meeting attendees.

**618 Environmental Assessment of New Human Drugs in the US and EU – Lessons Learned**

*T.A. Verslycke, Gradient; T. Lunsman, Gradient Corporation / Ecological Sciences*

Market approval of new human drugs in two key markets, the US and the EU, requires an assessment of potential environmental risks associated with patient use. The framework for conducting environmental assessments (EAs) of new human drugs in these markets, however, is not harmonized. As a result, the scope, cost, complexity, and time needed to complete the EA requires careful and early planning by pharmaceutical companies to ensure compliance and a timely filing. New human drugs may also have specific properties (*e.g.*, anti-infective, endocrine active, ionizable, low solubility) that trigger the need for a more tailored EA. Currently, guidance by the US Food and Drug Administration (FDA) and the European Medicines Agency (EMA) for conducting tailored assessments is limited, leaving substantial room for interpretation and professional judgment. Using several case studies, this presentation will illustrate technical challenges and successful approaches for conducting tailored EAs for new human drugs in the US and the EU. We will also make recommendations to streamline and harmonize approaches to tailored EAs given current available guidance and state-of-the-science. For example, an approach will be presented for considering existing environmental exposures (*e.g.*, exposures resulting from veterinary and human drug uses and/or natural sources) when conducting an EA for endocrine active and anti-infective drugs.

**619 Environmental Assessment Compliance Under FDA’s New Guidance for Drugs with Estrogenic, Androgenic, or Thyroid Activity**

*D.R. Davila, AbbVie / Toxicology; A. Soli, AbbVie / Preclinical Studies; R.T. Williams, Environmental Science & Green Chemistry Consulting, LLC; H.O. Krueger, EAG Laboratories; S. Schneider, EAG Laboratories; W. Bracken, AbbVie, Inc.*

AbbVie is developing a small molecule drug with effects on the endocrine system. The expected concentration (EIC) at the point of entry into the aquatic environment was below the 1 ppb criterion for categorical exclusion under FDA’s Guidance for Industry on the Environmental Assessment of Human Drug and Biologics Applications (July 1998). However, extraordinary circumstances applied given the hormonal activity of the molecule, which became subject to FDA’s Questions and Answers Regarding Drugs with Estrogenic, Androgenic, or Thyroid Activity Guidance for Industry (March 2016). AbbVie modeled the plasma concentration of the molecule in fish to inform the risk assessment, and found an effect ratio of 1200 (based on Huggett et al., Human Ecol. Risk Assess. 9:1789; 2003). This model assumes an effect ratio > 1000 might not warrant additional assessments in fish, but this model relies upon hydrophobicity to predict compound uptake and does not take into account factors such as hormonal activity. Environmental studies were requested by FDA. Consideration for the need for environmental studies included lack of examples of compounds with the same mechanism of action for “read across” purposes, and no data on environmental metabolism, fate, and transport of the AbbVie molecule. The environmental program was developed in a scientifically directed manner based on mechanism of action and in consultation with FDA. Studies and guidelines were as follows. Physicochemical properties (AbbVie internal methods), Partition Coefficient (OECD 107), Water Solubility (OECD 105), Activated Sludge Respiration Inhibition (OECD 209), Daphnia Magna Reproduction Test (OECD 211), Algal Growth Inhibition (OECD 201), Adsorption/Desorption on Soils & Sewage Sludge (OECD 106), Transformation in Aerobic and Anaerobic Aquatic Sediment Systems (OECD 308), Non-GLP Range Finding Trial for a Medaka Extended One Generation Reproduction Test (MEOGRT; OECD 240), Medaka Extended One Generation Reproduction Test (MEOGRT; OECD 240), Bioaccumulation in Fish (not triggered; OECD 305), Biodegradation in Activated Sludge (not needed; OECD 314B). Based on available data from these studies, the molecule is not expected to represent a risk to the aquatic environment. This presentation will review the process used for assessing environmental safety and the contributions and challenges associated with each study used to determine the fate and effects of AbbVie’s drug candidate.

**620 Improving the Interpretation of Results from the Fish Short Term Reproduction Test and the Medaka Extended One Generation Reproduction Test**

*H.O. Krueger, EAG Laboratories; S. Schneider, EAG Laboratories*

Higher tier endocrine tests like the FSTRA and MEOGRT are used to evaluate the potential for a chemical to cause endocrine disruption in fish. While variables such as fertility, fecundity, intersex and sex reversal have been identified as apical endpoints, other endpoints are used to evaluate mechanistic outcomes. Mechanistic endpoints generally include secondary sex characteristics, vitellogenin, gonad pathology and plasma steroids. While guidance documents provide performance criteria and statistical methods for the analysis of these variables, there is little guidance on how to integrate all the variables into an overall strength of evidence assessment to determine whether a chemical has endocrine activity, or if it should be considered an endocrine disruptor (i.e., has adverse health consequences for individuals or populations). Not only is it important to evaluate statistically significant trends, but equally important is to determine whether the magnitude of the responses are statistically significant and biologically relevant relative to controls. We argue that the pattern of the response is equally important to the response of an individual variable. It is also important that variables are weighted in considering their importance in an overall pattern of responses. Jensen and Ankley (2014) provide guidance on breaking out results into overt toxicity, apical endpoints, and mechanistic endpoints for FSTRA studies, while Borgert et al (2011) have used weight of evidence methodology to evaluate endocrine activity across suites of studies. We have built on these methodologies to compare responses of known endocrine disruptors to the test chemical in order to identify signature patterns of responses of known ER-agonists, AR-agonists, or AR-antagonists for fish FSTRA and MEOGRT. Such an approach helps prevent using spurious results to draw erroneous conclusions in evaluating endocrine disruption in fish.

## California Oil Spills: Impacts on Habitat and Wildlife

**621 Overview of impacts to natural resources from the Refugio Beach Oil Spill, Santa Barbara, California**

*M.J. Anderson, Department of Fish and Wildlife / Office of Spill Prevention and Response; J. Marek, US Fish and Wildlife Service; L. Sullivan, NOAA / ORR / ARD; A. MacFadyen, NOAA / ORR; G.F. Baker, NOAA / ORR / ARD*

Following the Refugio Beach Oil Spill, May 19, 2015, along the Gaviota Coast, state and federal trustee agencies pursued a cooperative natural resourcedamage assessment (NRDA) with the responsible party, Plains, LLC. The goal of the assessment was toquantify injuries to wildlife,habitat, and lost uses of those resources,and then to determine how to best restore the resources and compensate for the losses. In the course of the NRDA, the trustees conducted over 50 studies. This presentation provides an overview of the injuries assessed, including impacts to birds, mammals, fish, shoreline and subtidal habitats, as well as human recreation. The ultimate goal of the trustees is to restore and compensate for the injured resources. Following public outreach efforts, restoration projects will be proposed for implementation along the Southern California coastline.

**622 Applying Multiple Forensic Tools to Distinguish Spilled Pipeline Oil from Natural Seeps Following the Refugio Beach Oil Spill**

*G.F. Baker, NOAA /ORR / ARD; D. Valentine, Valentine Scientific and Consulting Services, Inc.; C. Reddy, Makepeace Environmental Solutions, LLC; S.A. Stout, NewFields Environmental Forensics Practice*

During the 2015 Refugio Beach Oil Spill in Santa Barbara County, CA, an estimated 190,000 liters of Monterey formation crude oil spilled from an onshore pipeline and flowed into the surf zone. Once in the ocean the oil was transported by currents, waves, wind, and other natural processes to nearshore, offshore, and subtidal zones. Some of the oil stranded on the shore and was found more than 200 kilometers from the spill site; some oil mixed in the nearshore and sank. Oil that was not recovered during response operations was gradually altered by various weathering processes. Numerous productive natural seeps release oil and natural gas from the seafloor in the Santa Barbara Channel region; similar seeps occur in nearshore zones throughout the Southern California Bight. Since the crude oil being transported in the Line 901 pipeline at the time of the spill was derived from offshore oil extraction platforms in the Santa Barbara Channel, forensically characterizing and identifying the provenance of oil found in the environment after the spill required the use of several forensic techniques and tools to distinguish spilled oil from natural seep oils. Natural seep oils have distinguishable characteristics and have been studied extensively by the U.S. Geological Survey and others. Despite originating from common subsea geological formations, careful analysis and interpretation using multiple lines of evidence provided the means to fingerprint samples of stranded oil, floating oil, and oil in other matrices, and reveal the transport and fate of oil spilled from the Line 901 pipeline.

**623 Polycyclic aromatic hydrocarbon uptake and forensic results in three beach invertebrate tissues and porewater – Refugio State Beach Oil Spill, 2015**

*B.M. Joab, CA Dept. of Fish and Wildlife, Office of Spill Prevention and Response / Scientific Branch; J. Dugan, University of California Santa Barbara / Marine Science Institute; D. Hubbard, University of California, Santa Barbara / Marine Science Institute; B. Duke, R.M. Donohoe, California Department of Fish and Wildlife / Office of Spill Prevention and Response; G.F. Baker, NOAA / ORR / ARD*

Sediment porewater and three sandy beach invertebrate species from Santa Barbara County beaches affected by the 2015 Refugio Beach oil spill were analyzed for polycyclic aromatic hydrocarbons (PAHs). A distinguishable PAH pattern was identified in tissue and porewater samples collected at several locations and multiple time points post spill. Significant correlations between porewater and tissue residues were identified. The most elevated PAH concentrations were observed in beach hoppers (*Megalorchestia spp.*), and the results showed elevated PAH concentrations persisted up to 4 months post spill in some locations, a longer duration than was observed in the sand crabs (*Emerita analoga*) or polycheates (*Thoracophelia spp.*). Sand crabs took up PAHs rapidly after the spill, within hours to days, but also appeared to have metabolized them rapidly. Forensic chemistry matches were identified between the source oil, taken near the ruptured oil pipeline, and multiple tissue types, as well as porewater samples. Beach hoppers and porewater served as useful monitoring media for documenting decreasing trends of PAHs in sandy beaches following this spill event.

**624 Population responses of sandy beach talitrid amphipods to the Refugio Beach Oil Spill, Santa Barbara County, 2015**

*J. Dugan, D. Hubbard, University of California, Santa Barbara / Marine Science Institute; B.M. Joab, CA Dept. of Fish and Wildlife, Office of Spill Prevention and Response / Scientific Branch; N. Schooler, K. Emery, University of California, Santa Barbara / Marine Science Institute; B. Duke, California Department of Fish and Wildlife / Office of Spill Prevention and Response*

Open coast sandy beaches in California harbor a rich intertidal community of macroinvertebrates, including talitrid amphipods. The talitrid amphipods or beach hoppers *(Megalorchestia spp.*) are important intertidal animals of open coast sandy beaches on the California coast. These nocturnal animals burrow in the damp sand of the upper intertidal zone in the day and emerge at night to feed on stranded macroalgae, such as giant kelp and feather boa kelp. They are dominant consumers of drift macrophytes or wrack on beaches in California and their feeding activities contribute to detrital processing and nutrient cycling. To evaluate possible injury to beach ecosystems resulting from the 2015 Refugio Beach oil spill in Santa Barbara County, we surveyed populations of beach hoppers on a number of affected beaches. Surveys were conducted at a range of beach locations and at multiple time points following the spill. Significant declines in beach hopper population abundance and biomass were observed at affected beaches in June 2015 when compared to available baseline data. Populations of beach hoppers continued to decline through summer 2015, likely due to continued oil spill cleanup activities. Results of surveys in June 2016 and 2017 suggest recovery of talitrid populations was protracted at beaches affected by the oil spill.

### 625 Development of a Polycyclic Aromatic Hydrocarbon Bioassay Using Sand Crabs (Emerita analoga) following the Refugio Beach Oil Spill, Santa Barbara, CA

*B.M. Duke, California Department of Fish and Wildlife / Office of Spill Prevention and Response; B.M. Joab, CA Dept. of Fish and Wildlife, Office of Spill Prevention and Response / Scientific Branch; J. Dugan, D. Hubbard, University of California, Santa Barbara / Marine Science Institute; R. Donohoe, California Department of Fish and Wildlife / Office of Spill Prevention and Response; S. Clark, Pacific EcoRisk / Marine Science Institute*

When developing toxicity bioassays for the purpose of oil spill natural resource damage assessment (NRDA), it is important to take into consideration key properties of polycyclic aromatic hydrocarbon (PAH) compounds, and to utilize appropriate organisms whenever possible. Therefore, an exposure scenario related to an oil spill event should take into consideration solubility, declining concentrations, and temperature. These parameters are important because each effects how PAHs interact once introduced into the marine environment. Similarly, care must be taken to select the appropriate organism(s) for use in toxicity bioassays. These organisms should be indicators of ecosystem health, available for collection, indigenous (if possible), and of a known age class. Additionally, these organisms should exist throughout a broad geographic range and should be easy to collect, sort by size, and maintain in a laboratory. For these reasons, *Emerita analoga* was selected for this bioassay.

### 626 Surf Zone Water and Beach Porewater Chemistry Following the Refugio Beach Oil Spill Indicate Effects to Fish and Invertebrate Early Life Stages

*R.M. Donohoe, California Department of Fish and Wildlife / Office of Spill Prevention and Response; G.F. Baker, NOAA / ORR / ARD; B.M. Joab, B. Duke, California Department of Fish and Wildlife / Office of Spill Prevention and Response*

During the 2015 Refugio Beach Oil Spill in Santa Barbara County, CA, Monterey formation crude oil spilled from an onshore pipeline and an estimated 190,000 liters entered the surf zone, where it actively mixed with seawater and was transported along the shoreline and offshore. Immediately following the spill, dead adult fish and invertebrates were observed in the spill affected area. Early life stages of many marine aquatic animals were present at the time of the oil spill that have been shown in previous studies to be sensitive to adverse effects from oil exposure. To evaluate exposure, water samples were collected from several locations between Gaviota State Beach and Carpenteria State Beach from May to September 2015. Elevated concentrations of polycyclic aromatic hydrocarbons (PAHs) and total petroleum hydrocarbons (TPH) were measured in the surf zone water and beach porewater samples collected near the release, declining over space and time. To investigate toxicity to early life stages, sand crab megalopae (*Emerita analoga*) and larval inland silverside (*Menidia beryllina*) 6-7 day static renewal bioassays were conducted. A high energy water accommodated fraction (HEWAF) mixture of the source oil and seawater was prepared and used in the laboratory bioassay studies to simulate surf zone contaminant exposure conditions. The oil-water proportions in the HEWAF preparations were designed to generate PAH exposure conditions that bracketed the measured concentrations in field collected water samples at the time of the spill. PAH composition and concentrations of the HEWAF were chemically analyzed to confirm that the bioassay exposures generally mirrored those shown to have occurred in the nearshore environment after the spill, based on chemical analysis of field collected water samples. Bioassay results indicated PAHs and TPH concentrations in surf zone water and porewater were lethal to early life stages of fish and invertebrates.

### 627 Effects of oiling on the seagrass, Phyllospadix torreyi, as a result of the Refugio Beach Oil Spill, Santa Barbara County, 2015

*N. Cosentino-Manning, NOAA Fisheries Restoration Center; S. Kimura, J. Altstatt, Tenera*

On May 19, 2015, crude oil spilled from a pipeline rupture on land and entered the surf zone and spread to nearshore habitats in the area of Refugio State Beach, Santa Barbara County, California. Oil from the spill entered sensitive marine habitats, in particular beds of the surfgrass, *Phyllospadix torreyi*, a marine angiosperm that grows abundantly in the low-intertidal/shallow subtidal. Surfgrass is one of the most productive marine primary producers, and provides important shelter, foraging areas, and nursery habitat for fishes and invertebrates, such as the commercially important California spiny lobster. Because of its importance, researchers studied the effects of the oiling on this species of surfgrass. Researchers observed a significant change in the condition of the surfgrass leaves beginning two months after the spill. Notably, the surfgrass leaves turned in color from a typical emerald green to yellow, brown, and black. In addition, the leaves were brittle and broke apart easily when pulled by hand. Quantitative surveys over the next year further assessed the health and condition of surfgrass and associated algae that had also became discolored. Quadrats, transects, and sampling by paddle board, snorkel, and SCUBA surveys were utilized to document the degree of injury to intertidal and shallow subtidal surfgrass beds. Effects were measured at all sites where there was heavy oiling.

### 628 Impact of the Refugio Beach Oil Spill on Two Surf Zone Fish: Surfperch (*Embiotocidae*) and California Grunion (*Leuresthes tenuis*)

*D. Witting, NOAA / NMFS / Restoration Center; R.M. Donohoe, California Department of Fish and Wildlife / Office of Spill Prevention and Response; L. Sullivan, NOAA / ORR / ARD; R.W. Ricker, NOAA / Office of Response and Restoration; B. Anulacion, G.M. Ylitalo, NOAA Fisheries / Northwest Fisheries Science Center; K. Martin, Pepperdine University / Department of Biology*

During the May 2015 Refugio Beach Oil Spill, 190,000 liters of crude oil flowed into the surf zone. Fish in the nearshore environment were exposed to the oil by direct contact, and via consumption of contaminated prey. As part of the subsequent Natural Resource Damage Assessment, studies were conducted to examine the impacts of oil exposure on two groups of surf zone fish: surfperch (Embiotocidae) and California grunion (*Leuresthes tenuis).* A quantitative assessment of exposure was conducted by measuring levels of polycyclic aromatic hydrocarbon (PAH) metabolites in surfperch bile. Five days after the spill, surfperch were collected at Refugio State Beach, a heavily oiled area, Gaviota State Beach, a lesser oiled area, and Campus Point Beach, an area with potential seep oil exposure. Surfperch had significantly elevated levels of biliary PAH metabolites at Refugio State Beach, compared to the other locations. Effects on early life stages of the California grunion were evaluated due to their unique life history which includes burying fertilized eggs on beaches where they incubate until being washed out to sea two weeks later. Grunion beach spawning events were observed in June 2015 and egg clutches were collected 5-7 days later at two beaches in the spill affected area and at two relatively unoiled beaches. Spawning observations and egg clutch collections were repeated one year later. Field collected eggs were incubated in the laboratory, then triggered to hatch by seawater agitation. Hatching behavior and survival were monitored. In general, eggs from grunion clutches that were collected from beaches that were exposed to oil had lower hatch rates, compared to clutches that were collected from beaches that were not exposed to oil. These studies demonstrated that surf zone fish were exposed to oil and indicated that adverse effects to early life stages of fish occurred.

# Environmental Risk Assessment of UV Filters in Freshwater and Marine Environments

**629 Environmental Risk Assessment of UV Filters in Freshwater and Marine Environments: State of Science and Challenges**

*I. Davies, Personal Care Products Council / Science*

UV filters are ingredients in personal care products that protect consumers against the adverse effects of UV radiation. UV filters are also used as photoprotective agents in other products, such as plastic and apparel items. Organic UV filters have diverse chemistries and moieties. Inorganic UV filters are metallic and can be nanoscale or non-nanoscale. UV filters such as benzophenones share chemistries with naturally occurring compounds. For example, oxybenzone is a natural compound produced by higher plants. It is crucial to appreciate these various chemistries and sources when assessing environmental fate and effects of UV filters. Environmental exposure to UV filters occurs *via* point and diffuse pathways. Point exposure occurs when UV filters wash-off bathers. This includes exposure to coastal sediment when, for example, aerosolized UV filters are applied to people on a beach. Diffuse exposure occurs when UV filters are washed-off down the drain and enter the waste water system. UV filters have been detected at low ng/L to µg/L levels; mainly in the marine environment. However, more monitoring studies are needed before a clear picture of exposure can be painted; the first step in an environmental risk assessment. When UV filters enter the aquatic or marine environment they are subject to various fate and transport mechanisms. Very little is known about these mechanisms, yet such data are essential to understand the concentration and timing of potential exposure of organisms to UV filters and/or their metabolites/degradation products. Further fate and transport research is therefore required to establish partitioning of UV filters between water and organic phases, biotic and abiotic degradation pathways and bioaccumulation of these materials. In addition to the limited amount of data regarding the concentration of UV filters in the environment, very few ecotoxicological data are available to assess whether UV filters are hazardous at environmentally relevant concentrations. Although some laboratory ecotoxicological studies have been conducted for a handful of UV filters, many questions remain over the extrapolation of these studies to the environment. Overall, huge data gaps exist for UV filters with regard to exposure and toxicological hazards, including endocrine activity. More research is therefore required to fill these data gaps and establish the risk these materials pose to organisms residing in the marine and aquatic environment.

**630 Targeted and non-targeted analysis of coastal contaminants in coral reefs of Oahu, Hawaii**

*M. Gonsior, A. Heyes, C.L. Mitchelmore, C. Clark, R. Younger, University of Maryland Center for Environmental Science / Chesapeake Biological Laboratory; P. Schmitt-Kopplin, Helmholtz Zentrum Munchen*

Coastal water samples and sediments were collected in shallow waters near public beaches, and waters beyond the barrier reef using a small vessel along the coast of Oahu, Hawaii. The objective of this study was to investigate the presence of known anthropogenic contaminants, for example polycyclic aromatic hydrocarbons (PAHs), as well as screening for suspected contaminants using a non-targeted ultrahigh resolution Fourier transform ion cyclotron resonance mass spect5rometric (FT-ICR MS) technique. Results showed that of the 49 PAHs examined, some were present at all beach locations, although the composition of the PAHs differed slightly. These findings are of concern as PAHs have been shown to concentrate and cause impacts in corals. The non-targeted approach revealed a large diversity of aliphatic and aromatic sulfonic surfactants, their co- and by-products, which highlights that coastal waters of Hawaii, and in particular near-shore coral reefs, are exposed to a multitude of contaminant stressors. The linear alkyl benzene sulfonates (LAS) are of particular concern, because they showed in previous studies very high toxicity to corals. These findings suggest corals off Oahu, Hawaii are exposed to a variety of potentially toxic compounds, adding to the stresses already imposed by increased ocean temperature.

**631 Concentration of the UV-filters Oxybenzone and Octinoxate in Coral Tissue (*Porites* spp.), Surface Water and Sediment Samples from Oahu, Hawaii**

*C.L. Mitchelmore, University of Maryland Center for Environmental Science / Chesapeake Biological Laboratory; K. He, E. Hain, University of Maryland Baltimore County / Department of Chemical Biochemical and Environmental Engineering; A. Feerick, University of Maryland Baltimore County; R. Younger, A. Heyes, M. Gonsior, L. Blaney, University of Maryland Baltimore County / Department of Chemical Biochemical and Environmental Engineering*

UV-filters contained in sunscreen products, notably oxybenzene (BP-3) and octinoxate (OCX), have been the focus of recent legislation in Hawaii, USA, due to concerns regarding their potential toxicity to coral reefs. However, limited information is available on the environmental concentrations of these chemicals in seawater surrounding Hawaiian coral reefs, and no data have been reported for the environmental distribution of these chemicals in coral tissue and sediment from Hawaii. To address these knowledge gaps in October 2017 we collected surface seawater, coral tissue (*Porites* spp.) and sediment samples from 19 sites in Oahu, Hawaii that differed in potential inputs of sunscreen-derived UV-filters. Nearshore and offshore sampling sites were chosen at Waikiki Beach (popular tourist destination), Kaneohe Bay (tourist and mixed use site), and Ka'a'awa (chosen as a 'reference' location). An additional study included sampling seawater and sediment at a variety of beach parks around Oahu. The UV-filters, BP-3 and OCX were measured using LC-ESI-MS/MS techniques. BP-3 was detected in seawater at all 19 sites, but the aqueous concentrations were less than 10 ng $L^{-1}$ at 12 out of the 19 sites. At Waikiki Beach, BP-3 concentrations were as high as 136 ng $L^{-1}$. Similarly, BP-3 was detected in all coral tissue samples at concentrations of 17-265 ng $g^{-1}$ (dry weight; dw). However, BP-3 was only measurable in sediment samples at 7 out of 19 sites at < 1 ng $g^{-1}$ (dw). No quantifiable levels of OCX were recorded for the seawater or coral samples, although OCX was quantified in sediment samples from Kaneohe at concentrations less than 13 ng $g^{-1}$ (dw). This study provides insight as to the environmentally relevant concentrations in seawater and sediment in Hawaiian coral reef locations. In addition, this study is the first to report concentrations of UV-filters in corals from the USA. These data provide an important baseline for future risk assessments of the potential toxicological effects of UV-filters on coral reefs and other marine organisms in Oahu, Hawaii.

**632 Anaerobic wastewater and marine microbial communities demethylate pharmaceuticals and the UV filter oxybenzone with metabolite accumulation**

*S. Wolfson, Rutgers University; A. Porter, Rutgers University School of Environmental and Biological Sciences; T. Villani, J. Simon, Rutgers University; L.Y. Young, Rutgers University / Department of Environmental Sciences*

Pharmaceuticals and personal care products (PPCPs) can be metabolized by microbes, releasing not only the intact PPCPs but also their metabolites to the environment. The multitude of PPCPs makes studying each microbial metabolism an arduous task. We propose that predicting microbial metabolism of PPCPs during wastewater treatment is best understood in the context of shared chemical structure. We recently described a methanogenic enrichment culture from anaerobic wastewater sludge that readily demethylates the common pharmaceutical naproxen (Aleve) to 6-O-desmethylnaproxen, with no loss of the metabolite observed. In this culture, methane was generated at stoichiometric amounts to naproxen demethylation, indicating that the methyl group removed from naproxen stimulates a complex microbial community. The natural methoxy aromatic compounds syringic acid and vanillic acid were also readily demethylated, and this shared metabolism prompted an examination of other methoxy aromatic xenobiotic compounds. In the present study we challenged the methanogenic wastewater culture with the methoxy aromatic UV filter oxybenzone and observed demethylation to benzophenone-1, which itself is an estrogenic contaminant. In addition, the wastewater culture transformed the pharmaceutical guaifenesin (Mucinex) to a novel demethlated metabolite whose environmental and health impacts are yet unknown. A second culture from sulfidic marine sediment was established to simulate anoxic environmental sediment receiving pharmaceutical contamination. Again, the natural and PPCP methoxy aromatic compounds were readily demethylated with accumulation of the metabolites. The demethylation of oxybenzone to the contaminant benzophenone by both cultures emphasizes the importance of methoxy aromatic demethylation in evaluating PPCP risk. This study suggests that methoxy aromatic PPCPs are readily transformed to demethylated metabolites both during anaerobic wastewater treatment and in the environment, and their associated metabolites may accumulate in anoxic environments.

**633 Direct dosing of an oxybenzone-based sunscreen formulation causes negative effects within the physiology and microbiome of two coral species**

*N. Bean, University of Hawaii at Manoa; R.B. Banister, Mote Marine Laboratory / Coral Health and Disease; M.S. Henry, P. Blum, Mote Marine Laboratory / Ecotoxicology; K.L. Imhof, Mote Marine Laboratory / Coral Health and Disease; R.H. Pierce, Mote Marine Laboratory / Ecotoxicology; E. Muller, Mote Marine Laboratory / Coral Health and Disease*

Reef-building corals are a vital component of biological diversity within the oceans and provide an economic engine for many coastal communities. Yet corals are experiencing high rates of mortality from a broad range of global and local stressors. Personal-care products, such as oxybenzone-based sunscreen may be one of them. We exposed colonies of *Montipora capricornis* and *Acropora cervicornis* to a range of oxybenzone concentrations (3 mg/L, 0.3 mg/L, 0.04 mg/L, 0.007 mg/L BP3, 0 mg/L oxybenzone) by dosing aquaria water with a particular sunscreen formulation every 48 hours for 17 days. To quantify the physiological impacts from exposure, we conducted daily visual assessments of the coral health, measured photochemical efficiency of photosystem II within the algal symbionts of the corals, the growth rates of *M. capricornis*, and the mortality rate of both species through time. We also measured the concentration of *Vibrio* sp. bacteria within the water column and within the mucus of *A. cervicornis* using selective media for this bacterial group. *Vibrio* concentrations were measured prior to dosing, 24 hours after dosing, and at the end of the experiment. After 17 days, *A. cervicornis* in the 3.0 mg/L and the 0.3 mg/L oxybenzone treatments and all of the *M. capricornis* exposed to sunscreen were either visually bleached or pale. Growth rates of *M. carpricornis* were also reduced at oxybenzone concentrations of 3 mg/L and 0.3 mg/L. All of the corals in the 3 mg/L oxybenzone treatment suffered 100% mortality within nine days. There was also a reduced maximum electron transport rate within the 3 mg/L oxybenzone treated *M. capricornis* and *A. cervicornis* and a reduced maximum effective quantum yield for *M. capricornis* in the 3 mg/L oxybenzone treatment. Prior to dosing, the seawater and the coral samples both contained less than one colony forming unit (CFU) per 150 ul of sample. After dosing, the number of *Vibrio* bacteria within both sample types significantly increased. However, concentrations reduced back to pre-treatment levels for both seawater and coral samples by the end of the experiment. In general, *M. capricornis* was more sensitive to the effects of the oxybenzone-based sunscreen compared with *A. cervicornis,* although both species were negatively affected by the exposure. Our results show that some oxybenzone-based sunscreen formulations can alter the host microbiome, reduce coral health and growth rate, and increase mortality rates of two coral species.

**634 UV filters contribution to coral bleaching? Laboratory chronic toxicity testing and concentration monitoring in the lagoon of the Moorea island**

*M. Leonard, L'Oréal SA / Recherche Environnementale; J. Fel, L'Oréal Research & Innovation / Environmental Research; A. Bensetra, L'Oréal Research & Innovation / Dpt Analytical Chemistry; S. Mezzache, L'Oréal Research & Innovation / Analytical Chemistry; E. Beraud, C. Ferrier Pages, Centre Scientifique de Monaco; B. Bonnet, L'Oréal / Analytical Chemistry; D. Allemand, Centre Scientifique de Monaco; S. Planes, French National Center for Scientific Research*

Some studies have reported that certain UV filters (mostly 4-methylbenzylidene-camphor, benzophenones and octylmethoxycinnamate) contained in sunscreen lotions and washed off by swimmers could trigger coral bleaching. Suspicion has been extended to all organic UV filters present in sunscreens products. The present study will report on the laboratory coral chronic toxicity assessment of some UV filters used in sunscreens (Octocrylene, Avobenzone, Terephtalylidene-dicamphor sulfonic acid, Silatrizole, Ethylhexyltriazone and the mineral UV filter Zinc oxide). Herbicides (Monuron and Diuron) and Tributyltin were used as reference toxic compounds. Cultured coral nubbins of the species *Stylophora pistillata* were exposed for 5 weeks to low UV filters concentrations (from 10 µg/L to 5 mg/L), but still higher than those reported in natural sea waters. Nubbins were exposed in 15-liters aquariums with weekly water renewal. UV filters concentrations were monitored all along the exposure period with automated solid phase extraction with UPLC-UV detection. Bleaching was visually observed and Photosystem II inhibition of the symbiotic zooxanthella was measured with Pulse Amplitude Modulated fluorometry, 5 days a week for 5 weeks. To enlarge the scope of these UV Filters impact assessment on aquatic biodiversity, additional ecotoxicity testing was performed with complementary soft and marine planktonic organisms such as micro-algae (chlorophytes and diatoms), daphnids crustaceans, fish embryos, marine bacteria and sea urchin larvae. Meanwhile, passive samplers were used to quantify aquatic UV filters concentrations at different sites of the lagoon of the Morea Island, in the French Polynesia. These chronic toxicity and field monitoring data provide new insights into the assessment of UV filters impact on coral reefs.

**635 Dibenzalacetone and its Derivatives: Sunscreen Agent (An Active Ingridient in Suncreens)**

*T.L. Adewunmi, Chemical Society of Nigeria / Chemistry Department, University of Lagos*

Sun energy is responsible for the growth of vegetation on which all life depends, directly or indirectly. Too much exposure to it can lead to adverse environmental health effect such as skin rashes, skin cancer, eye cataract, sun burn to mention a few. Sun protection is a significant public and environmental health issue, and sunscreens play an important role in the management of this risk. Sunscreens are agents that are designed to suppress the effect of sun radiation on the skin. An important component of sunscreen formulation is dibenzalacetone and its derivatives because of their ability to absorb and reflect UV radiation without adverse effect. Sunscreens utilize dibenzalacetone due to the fact that it absorbs UV rays, preventing them from absorbing into the skin itself. Other chemicals within sunscreen include those that actually reflect UV rays, pairing up with absorbers like dibenzalacetone to prevent as much skin absorption as possible. Dibenzalacetone is a highly potent chemical that absorbs UV rays, making it the ideal ingredient for sunscreens. In fact, dibenzalacetone is a leading ingredient in most commercial sun protection products, known for its highly stable and predictable properties. The chemical is also used because its stability allows it to be paired with other compounds commonly found in sunscreen, making SPF (Sun Protection Factor) levels easy to adjust. In this research study, some analogues of dibenzalacetone viz: 3,3'-dichlorodibenzalacetone, 4,4'-dichlorodibenzalacetone, 4,4'-diflorodibenzalacetone, 3,3'-dihydroxy-4,4'-methoxydibenzalacetone were prepared. The compounds were synthesized by adol condensation using 2 moles of the respective substituted benzaldehyde and 1 mole of acetone in the presence of sodium hydroxide. The compounds were characterized using melting point, FR-IR, UV-visible spectroscopy. The infra-red spectra of the compounds confirm the functional groups expected. The presence of vibrational peaks in the range 1442 – 1650 $cm^{-1}$ are evidence of C=C. The stretching frequency observed in the range 1642 – 1650 $cm^{-1}$ are attributed to C=O in the compound. The small peaks around 1572 – 1888 $cm^{-1}$ shows band position of aromatic ring. The wavelength of maximum absorption for the compound ranged from 278 – 324 nm while the molar extinction coefficient ranged from 5080 – 19520 nm. The spectroscopy data for the compounds were correlated with substituent constant using a form of Hammett equation.

**636 Balancing Human Health Benefits of UV Filters Versus Potential Environmental Risks**

*J. Sirois, CHPA / Regulatory & Scientific Affairs*

Regular sunscreen use is a proven method of reducing the skin damaging effects of UV radiation and can prevent melanoma and other non-melanoma skin cancers. Professional and medical organizations including the American Cancer Society, the American Academy of Dermatology and the Centers for Disease Control and Prevention recommend the use of a broad-spectrum sunscreen, or one that protects against both UVA and UVB radiation. Dermatologists agree that the best sunscreen is the one that is used on a regular basis. Factors contributing to effective use of sunscreen include cost, skin feel, and product performance. In the US, a limited number of sunscreen active ingredients are available which provide broad spectrum protection. Consumer preference is an important determinant of use and reducing the number of available sunscreens is very likely to result in reduced use, a situation that could lead to increased skin damage and skin cancer diagnoses. To date, a very limited number of studies have associated particular sunscreen active ingredients with harm to coral reef populations. These studies have been conducted under artificial conditions in a lab setting, have a number of inherent methodological limitations and have yet to be replicated under real-world conditions. A much larger body of work exists pointing to global climate change as the dominant contributor to coral decline worldwide. Many of these studies demonstrate the occurrence of coral reef bleaching irrespective of whether an area experiences high levels of human activity such as swimming, strongly suggesting sunscreens are not primarily responsible for the bleaching events. When translating science into governmental policy, decisions should be based on sound data. When viewed in its entirety, the currently available evidence on the causes of coral reef bleaching and mortality, both in HI and the world over, overwhelmingly demonstrates that climate change, ocean acidification and runoff are primarily responsible for coral bleaching. Banning individual sunscreen ingredients is unlikely to result in a significant benefit to coral reef populations while conversely creating the potential for significant public health implications associated with enhanced exposure to UV radiation. Sunscreens marketed as being “reef safe” apparently base this claim on the absence of a particular ingredient(s) and there is currently no regulatory authority or governmental body that recognizes this claim.

## Assessment and Monitoring of Risks to Aquatic Environments from Short-Term (Episodic) Contaminant Exposures

**637 An overview of the nature of episodic water pollution and implications for pollutant averaging periods to be protective of aquatic life**

*C.A. Mebane, USGS / Idaho Water Science Center; M. Elias, USEPA / Office of Water; J. Justice, USEPA / HECD; K. Gallagher, USEPA / Office of Water*

Contaminant concentrations and factors that modify their potential toxicity are time-varying in mid-size rivers and streams, depending on inter-annual, seasonal, or daily cycles, as well as stormwater-driven pulses. Short-term (< 1 day) contaminant exposures are difficult to monitor and can affect water quality. Aquatic life criteria in the USA intend to address the episodic nature of water pollution through a two-number criteria paradigm, in which different averaging periods are intended to account for time-varying exposures of different contaminant magnitudes. Using the Mancini kinetic model, toxic averaging times were calculated for a variety of acute tests, with mortality occurring in exposure times ranging from < 2 to >96 hours. However, with short-term acute exposures, delayed mortality can also be an important issue and the inability to account for delayed mortality following short-term exposures was a major limitation of most datasets examined. Averaging periods for acute criteria need to consider the commonness of episodic pollution events. The studies reviewed show short-term exposure to contaminants in stormwater runoff can be toxic to freshwater organisms, with several studies demonstrating episodic exposures of ≤3 hours could produce pronounced acute toxicity.

**638 Understanding episodic exposures: Acute and latent effects of zinc on Ceriodaphnia dubia and Oncorhynchus mykiss**

*J.A. Steevens, N. Wang, C.D. Ivey, USGS / Columbia Environmental Research Center; R. Gettler, USGS; C.A. Mebane, USGS/ Idaho Water Science Center*

Water pollution sources are often episodic, which results in time-varying concentrations in receiving waters. Runoff from built up or disturbed areas such as urban areas, highways, agriculture, or industrial, agricultural and mining operations can result in episodic pollution events. One of the challenges in assessing the effects of these pulsed exposures is that thresholds are often derived from acute 48- or 96-hour bioassays. A review of literature, from which time-to-effects in short-term (≤24 hour) bioassays or following pulse exposures could be sufficiently determined, shows that short-term exposures to a number of contaminants can be lethal to a variety of aquatic organisms. Additionally, several studies have reported that mortalities continue to accrue following short-term exposures to a metal, suggesting that evaluations of time-to-effects for metals may fail to consider delayed mortality. A series of experiments using the cladoceran *Ceriodaphnia dubia* and juvenile rainbow trout *Oncorhynchus mykiss* were conducted to evaluate the toxicity of zinc in up to 48-hour exposures with a cladoceran and in up to 96-hour exposures with rainbow trout, and to evaluate the latent mortality following the exposure to five or six concentrations of zinc. Test designs used a non-renewal test with the cladoceran for 1, 3, 8, 24, and 48-hour exposures and a static-renewal test with the trout for 1, 3, 8, 24, and 96-hour exposures (water renewal at 48 hours). Surviving organisms after the exposures were placed in the control water and latent mortality was monitored through the 48-hour experiment with the cladoceran and the 96-hour experiment with the trout. For the conventional acute exposures (48 hours with the cladoceran, 96 hours with the trout), surviving organisms after the exposures were placed in the control water and fed for 48 hours to determine whether latent mortality occurred. Results of these studies will be used to determine whether existing data are sufficient to demonstrate potential harm from brief, severe pulse exposures to toxicants, such as those that may occur during urban stormwater events. These results also give support to include provisions in water quality criteria framework to protect against brief or episodic conditions.

**639 A methodology to predict toxicity potential of an urban stormwater discharge**

*J.M. Diamond, C. Boschen, Tetra Tech*

Urbanized areas are sources of stormwater runoff that may contain numerous potential contaminants and have varied intensity and duration. Therefore, biological effects of urban stormwater discharges may not be adequately addressed using traditional toxicological approaches, which are based on prolonged, constant exposures to single chemicals. This presentation uses aspects of an approach developed in the Pellston workshop: *Simplifying aquatic assessments of chemical mixtures in urban environments* to evaluate toxicity potential of Chollas Creek, a heavily urbanized drainage in San Diego, CA that is stormwater-dependent. Rainfall data from 10 separate wet weather events between 2009 and 2014 were related with acute toxicity tests and Event Mean Concentrations at two sites for over 60 chemicals including dissolved metals, PAHs, pyrethroid, chlorinated, and organophosphorus pesticides, and PCBs. Each chemical concentration was converted to toxic units (TUs) based on *Ceriodaphnia* acute EC50s and chemicals were ranked in terms of their contribution to the overall sum of TUs (concentration additivity) for each wet weather event. In decreasing order, bifenthrin, zinc, copper, malathion, and benzo(a)anthracene contributed between 60 and 75% of the total TUs. All pyrethroids, copper, zinc, malathion, and PAHs contributed between 88 and 96% of the total TUs in each stormwater sample. Total TUs based on 6-12 hour exposure (the duration of stormwater events at this site) was

### 640 Improving the assessment of potential impacts from intermittent, short-term, effluent discharges to aquatic environments

*S.L. Simpson, CSIRO Land and Water / Centre for Environmental Contaminants Research; B.M. Angel, S. Stone, CSIRO Land and Water; M. Binet, CSIRO Land and Water / Centre for Environmental Contaminants Research (CECR); D.F. Jolley, University of Wollongong / School of Chemistry*

Determining the risk posed by intermittent, fluctuating and pulsed contaminant discharges to aquatic environments is challenging. Water quality criteria (WQC) and whole effluent toxicity (WET) test methods are the most frequently utilized assessment tools used to predict or assess toxicity of effluents following mixing with the receiving water. However, both WQC and WET approaches were developed to assess continuous rather than intermittent contaminant exposures. Conservative assessment outcomes are desirable owing to the often complex and fluctuating composition of effluents, the nature of receiving environments, and varying organism/receptor responses. However, highly over-conservative assessments of short-term discharges may result in unnecessarily high costs for treatment or remedial actions. In this presentation we discuss toxicity results from short term (e.g. 1 to 48 h pulses) and chronic (e.g. days to weeks, depending on species lifecycle) exposures to individual contaminants and complex contaminant mixtures across a range of freshwater and marine microalgae and invertebrates (amphipods, copepods). For the range of species and test conditions (contaminants and pulse durations), observed toxicity was generally proportional to the time-averaged concentration (TAC) of the contaminant (or % effluent), i.e. inversely varying pulse concentration and duration resulted in a similar level of effects. The medium-term pursuit of this research is to determine the conditions under which (i) WQC may be relaxed by a factor proportional to the TAC, and/or (ii) WET methods may be applied with effluent exposure durations that better match the receiving environment, and achieve protective but not overly-conservative outcomes. Due to the limited range of receptor endpoints (species, test outcomes) and effluent contaminant mixtures assessed to date, there remains uncertainties that impede recommendations for modified risk assessment approaches. Knowledge gaps include contaminant mixtures, organism life-stage sensitivity, and the timing of exposure (day or night). Ultimately this research will facilitate more reliable assessment and management of intermittent discharges, such as stormwater runoff and those from industrial facilities.

### 641 Predicting the toxicity of episodic (plused) exposures of copper and zinc

*R.C. Santore, Windward Environmental, LLC; J.H. Bisesi, University of Florida / Environmental and Global Health; A.C. Ryan, K.E. Croteau, Windward Environmental, LLC*

Metal toxicity to aquatic organisms has traditionally been studied by exposing organisms to a continuous concentrations for the duration of the toxicity test. This experimental design may be appropriate for discharges that are consistent for long periods of time (such as wastewater treatment plants). However, for discharges that are intermittent or time-variable continuous exposures may not be a realistic description of environmental conditions. Unfortunately, tools for understanding and predicting the effects of time-variable discharges have not been available to regulators and risk assessors. In this work we demonstrate that toxicity from time-variable exposures is reduced, compared to what would be expected from comparable continuous exposure conditions. For both copper and zinc, toxicity to sensitive aquatic organisms is shown to directly relate to exposure duration. The results from these tests show that comparable continuous exposures may overestimate toxicity by 10 or 100 fold. We also have developed a modeling framework for understanding and predicting toxicity from episodic exposures called the Biotic Ligand Episodic Exposure Model (BLEEM). BLEEM is an extension of the Biotic Ligand Model (BLM) that includes a time-variable damage and repair. Application of BLEEM to episodic copper exposures results in very good predictions of metal toxicity in time-variable and episodic exposures. BLEEM can be used as a regulatory and risk assessment tool for improving our understanding of the impacts of episodic metal exposures on aquatic life.

### 642 Preliminary Evaluation of Improved Toxicity Testing Methods for Episodic Discharges

*M. Colvin, SPAWAR Systems Center Pacific / Energy and Environmental Sustainability; G.H. Rosen, SPAWAR Systems Center / Energy and Environmental Sustainability; C. Stransky, Wood Environment & Infrastructure / Aquatic Sciences; N. Hayman, SPAWAR Systems Center Pacific / Energy and Environmental Sustainability; K. Kowal, San Diego State University Research Foundation*

Episodic discharges such as stormwater require environmentally-relevant, scientifically-defensible, and conservative toxicity test designs to assess potential for receiving water impacts. Permittees in highly industrialized areas are increasingly required to conduct 96-h (or longer) static toxicity tests on stormwater collected at end-of-pipe associated with events that are generally less than 24-h. Our team is currently evaluating alternative toxicity test designs for episodic exposures that would require minimal modification to standard methods, yet increase realism towards protection of beneficial uses from episodic discharges. Preliminary results associated with this work include those from chronic toxicity tests with purple sea urchin (*Strongylocentrotus purpuratus*) embryos and acute toxicity tests with the mysid shrimp (*Americamysis bahia*). The evaluations involved a comparison of standard USEPA protocols to a slightly modified exposure method using two common stormwater-associated toxicants, copper and zinc. Tests were performed under static (96-h continuous exposure) and pulsed exposures (time varying toxicant exposure. Following pulsed exposures, organisms were transferred to uncontaminated seawater for the remainder of the 96-h exposure period. To date, results with these species and endpoints suggest pulsed exposure median effective and median lethal concentrations are up to two orders of magnitude greater (i.e. less sensitive) than current recommended continuous approaches for these test methods. Additional considerations assessed during these studies included: (1) appropriate timing of the onset of a pulse during laboratory exposures – time zero or after an acclimation period in receiving water; (2) evaluation of different life stages of proposed test organisms; and (3) the potential for latent effects following the proposed pulsed exposure duration. This presentation will summarize results to date, and future plans to assess proposed Whole Effluent Toxicity test modifications within National Pollutant Discharge Elimination System requirements for episodic discharges.

### 643 A Multiple Line of Evidence Approach to Assess Stormwater Impacts from the Scripps Institution of Oceanography to Receiving Waters in San Diego, CA

*C. Stransky, Wood Environment & Infrastructure / Aquatic Sciences; R. Schottle, Wood Environment Infrastructure Solutions; K. OConnell, University of California San Diego / Environmental Affairs; M. Colvin, SPAWAR Systems Center Pacific / Energy and Environmental Sustainability; G. Rosen, SPAWAR Systems Center Pacific; J. VanVoorhis, K. Buckley, Wood Environment Infrastructure Solutions Inc*

The variable nature of stormwater runoff presents unique challenges with regard to accurately characterizing impacts to receiving waters.

A multiple line of evidence approach is needed to better characterize potential biological impacts and stressors of concern. The University of California's Scripps Institution of Oceanography (SIO) is situated on the Pacific Ocean adjacent to an Area of Special Biological Significance. Seawater from the research facilities and a public aquarium, as well as stormwater during wet weather, enters the ocean off SIO requiring an NPDES permit to monitor discharges from the facility during both dry and wet weather. Routine monitoring includes a suite of chemicals and toxicity tests in samples from several outfalls and the receiving water twice annually, and a biological community assessment and bioaccumulation study once every 5-years. To better understand impacts in the adjacent receiving waters, in situ toxicity tests, toxicity identification evaluations (TIEs), and a variety of other special studies have been integrated into the monitoring program over the past 12 years. Most recently, in 2018, a series of bioassays which altered the duration of the stormwater pulse (6, 26, and 96 hours) were also performed using the purple sea urchin *Strongylocentrotus purpuratus*. Although there are chemical constituents of potential concern in undiluted storm water runoff and toxicity has been observed in stormwater samples collected at the end of pipe, rapid mixing and dilution is evident in the immediate marine receiving waters. However, long term monitoring at this site has demonstrated limited to no toxicity observed in receiving water samples in the lab or in situ during wet weather. TIEs have identified copper and zinc as toxicants in stormwater at the end of pipe during wet weather, and toxic algae blooms as a source of toxicity in the receiving waters during a few dry weather events. The pulsed study found that duration of exposure did affect the outcome, with shorter exposures showing less of an effect. By reviewing the results of multiple lines of evidence collectively over time these enhanced special studies have provided a greater understanding of the impacts of wet and dry weather runoff to a dynamic marine receiving environment. This has allowed for better prioritization of BMPs, and has also shed light on the need to consider alternative approaches for assessment of episodic discharges such as stormwater runoff.

**644 Using integrative passive sampling devices to obtain more meaningful and cost-effective data on metal-associated impacts from stormwater runoff**

*N. Hayman, SPAWAR Systems Center Pacific / Energy and Environmental Sustainability; G.H. Rosen, SPAWAR Systems Center / Energy and Environmental Sustainability; I. Rivera-Duarte, SPAWAR Systems Center Pacific; E. Arias, SPAWAR Systems Center Pacific / Envrionmental Science; M. Colvin, SPAWAR Systems Center Pacific / Energy and Environmental Sustainability*

In many cases, stormwater compliance monitoring is labor intensive, expensive, and largely unsuccessful in providing the data needed to support stormwater management goals. To help address these issues, the time-integrative, heavy metal passive samplers, Diffusive Gradients in Thin film (DGTs), are being used to monitor stormwater runoff for copper, nickel, lead, and zinc. DGTs were co-located with traditional autosamplers within the stormwater conveyance systems at Naval Base San Diego (NBSD) to provide a direct comparison with composite sampling. In a more controlled fashion, DGTs were exposed in the laboratory to composite samples from NBSD stormwater conveyance systems. These controlled experiments showed increasing uptake over time (range = 1.5 to 24 h) for copper, cadmium, and nickel, with statistically significant positive, linear correlations ($r^2$>0.980) between time exposed and metal mass accumulated. However, it appears that the corresponding calculations of the DGT-labile fraction relative to the dissolved fraction fluctuated across the different exposure durations. In general, trends observed for DGT-labile measurements from the field were consistent with trends seen in the lab DGT exposures and traditional dissolved metal measurements from composite samples. Finally, time-weighted, average concentrations of copper and zinc from DGTs that were deployed for the first half and second half of a storm event were within 30% of measurements from DGTs that were deployed for the entire storm event in the same stormwater basin. Cumulatively, these results show promise for using continuous monitoring with DGTs as an approach that produces concentrations more representative of those in the receiving environment during episodic events than those concentrations measured from traditional grab or composite chemistry sampling.

## Non-Conventional Exposure Routes and Transport Media of Consumer Product Chemicals to Improve Environmental Policy

**645 High-throughput exposure modeling for 8000 Tox21 chemicals in the environment and in consumer products: Identification of dominant pathways**

*O. Jolliet, University of Michigan; P. Fantke, Technical University of Denmark / Quantitative Sustainability Assessment Division; L. Huang, University of Michigan / Dept of Environmental Health Sciences*

Near-field human exposure to chemicals in consumer products gains importance, since there is growing evidence that near-field chemical intakes can dominate overall exposures. However, exposure and toxicity characterization models used in life cycle impact assessment and comparative risk assessment are usually limited to chemicals emitted to the far-field environment. Thus, we developed a matrix-based framework based on the widely used USEtox model to integrate near- and far field chemical exposures and to identify dominant pathways. In this framework, the transfer rate constants are converted to direct transfer fractions from emission to receiving compartments. We connected near-field compartments including product, near-person air, with far-field compartments (e.g. air, water, soil), via wastewater and solid waste treatment plants. By inversion of the transfer fractions matrix, cumulative transfer fractions from products to various human receptors are obtained, also known as product intake fractions (PiFs), defined as the fraction of a chemical used in a product application that is cumulatively taken in by various receptors during use and disposal stages. The direct transfer fractions from different product and emission scenarios are calculated by 7 underlying models (skin surface layer, object surface layer, article interior, indoor air, food contact material, pesticide, direct environmental emission). Our framework was applied in batch mode to generate high-throughput exposure estimates of the PiFs for 8167 chemicals in Tox21 database via four pathways: near-field (residential), dietary, far-field industrial, and far-field pesticide. The total PiF summing users and non-users (i.e., general population) across all exposure pathways for the 8167 chemicals ranges from 1.9E-4 to 0.34, from 4.8E-6 to 0.19, and from 6.3E-6 to 0.22 via residential, dietary and far-field industrial pathways, respectively. In general, the residential pathway is associated with the highest total PiF, highlighting the importance of near-field chemical exposures. For semi-volatile compounds, dominant pathways include non-conventional pathways via dust, dermal gaseous uptake and mouthing for children. Results will also be presented for stochastic modeling of individual doses for another 9000 product-chemical combinations. The proposed tool is adequate for quantitatively informing exposure assessments for Chemical Alternatives Assessment, Life Cycle Assessment and Risk assessment.

**646 New Insights of Human Exposure to Consumer Product Chemicals from Comprehensive Chemical Profiles of Indoor Dust**

*D. Bennett, UC Davis / Public Health Sciences; C. Moschet, UC Davis / Civil and Environmental Engineering; H. Shin, UT Arlington; T.M. Young, University of California-Davis / Civil and Environmental Engineering*

Comprehensive chemical profiles of indoor dust may help better understand residential chemical exposure. Due to the wide range of chemicals found in consumer products, it is not easy to determine the full range of exposures to compounds emanating from consumer products in the home. SVOCs released from their original sources are fairly persistent indoors, and thus redistributed over time and partitioned to indoor air, settled dust, and other indoor surfaces. Dust is therefore an ideal media for identifying comprehensively what compounds are used in the home. Furthermore, for SVOCs with low vapor pressures, the levels in indoor dust are known to serve as an alternate marker of chemical exposure with common indoor sources (e.g., furniture, plastics, PCPs, pesticides, etc.). This study presents concentrations of a broad spectrum of semivolatile organic compounds (SVOCs) in household dust measured via a comprehensive analytical workflow. We quantified SVOCs in dust samples collected from 38 California homes by applying a combination of target, suspect, and non-target screening approaches to liquid chromatography quadrupole time-of-flight mass spectrometry (LC-QTOF/MS) and gas chromatography (GC)-QTOF/MS. A total of 257 compounds were detected in at least one sample and 170 compounds were detected in more than 50% of the samples. Of the 257 compounds, 168 compounds were unambiguously confirmed and quantified by reference standards and 135 compounds were detected for the first time in U.S. household dust. Median concentrations ranged from 5 to ~100,000 ng/g of dust. We utilized in vitro toxicology tests to identify newly detected compounds in our dust that have endocrine disrupting and neurotoxic potential. These identified compounds should further be studied in the context of consumer products, as they are most likely entering the home from consumer product use, and serves to broaden the landscape of chemicals that should be considered. This study demonstrates a novel analytical workflow to detect a large number of *known* and *unknown* SVOCs in indoor dust. Our results provide a comprehensive picture of the chemical fingerprint in dust which can be used in better understanding residential chemical exposure and associated adverse health effects.

**647 Our e-devices: Can't live without them but how are they contributing to our exposures to flame retardants?**

*M.L. Diamond, C. Yang, University of Toronto / Department of Earth Sciences; L.V. Nguyen, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; L. Jantunen, Environment and Climate Change Canada; S. Harris, Cancer Care Ontario & University of Toronto / Population Health and Prevention, Prevention and Cancer Control; V.H. Arrandale, Cancer Care Ontario & University of Toronto / Occupational Cancer Research Center; M. Venier, Indiana University / SPEA; L.E. Melymuk, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; W. Stubbings, Indiana University, Bloomington / School of Public and Environmental Affairs; S. Siddique, C. Kubwabo, Health Canada / Exposure and Biomonitoring Division; L. Bajard, Masaryk University RECETOX*

Electronic products are pervasive in just about everyone's lives, including children. They contain a wide array of hazardous chemicals including flame retardants. Their relatively short lifespan ensures a ready supply of e-waste that, in many jurisdictions, is mandated for handling in an environmentally sound fashion. We investigated electronic devices as sources of flame retardant exposure during their use and End-of-Life phases. In a residential exposure study of 51 women in Toronto and Ottawa, Canada, we measured concentrations of organophosphate esters (OPEs) and halogenated flame retardants (HFRs) in air and floor dust in their homes, on their hands, and the surfaces of their electronic devices. Also, 8 OPE metabolites were analyzed in the urine samples of 44 participants. Surface concentrations of OPEs and HFRs were significantly higher on handheld electronic devices (e.g., cell phone, tablet) than non-handheld devices (e.g., TV, desktop), except for BDE-209 and DBDPE. OPE concentrations on hands were most frequently correlated with concentrations on cell phones, whereas PBDEs, EHTBB and BEHTBP on hands were most frequently correlated with concentrations on laptops. ∑OPE concentrations on participants' cell phones were significantly correlated with levels of the corresponding metabolite in urine samples, driven mostly by TPhP. We also found that levels of TDCPP in dust and cell phones were significantly correlated with the corresponding urinary metabolite. The data suggest that cell phones are both sources of OPEs as well as indicators of exposure of OPEs and some HFRs. In an e-waste study in Ontario, Canada, we also measured concentrations of OPEs and HFRs in air and floor dust. Levels of BDE-209 were by far highest, followed by OPEs. Compounds in this dusty environment were found in inhalable particles. Total exposure was dominated by dust ingestion followed by inhalation. These exposures were relatively high and, in some cases, exceeded those working in the informal recycling sector of low income countries. Some exposures also exceeded reference doses. Electronic devices have profoundly changed our society. When assessing benefits and risks, we need to add the adverse effects arising due to chemical exposures from these devices during the use and End-of-Life phases and seek solutions to minimize those effects. The environmental consequences of our widespread use of electronic devices are even farther reaching.

**648 Exposure of Contaminants of Emerging Concern (CECs) and Other Chemicals in Urban Stormwater Runoff in the Conterminous United States**

*J. Masoner, USGS / Oklahoma Water Science Center; D.W. Kolpin, USGS / Central Midwest Water Science Center; P.M. Bradley, USGS / South Atlantic Water Science Center; D. Burden, R. Lowrance, J. Groves, USEPA / ORD / Robert S. Kerr Environmental Research Center; E.T. Furlong, USGS / National Water Quality Laboratory; M.L. Hladik, USGS / California Water Science Center; L.B. Barber, I.M. Cozzarelli, USGS / National Research Program; D.P. Krabbenhoft, USGS; W. Selbig, USGS / WI Water Science Center; K. Forshay, USEPA / ORD / Robert S. Kerr Environmental Research Center; W.A. Battaglin, USGS / CO Water Science Center; B. Williams, USGS / NJ Water Science Center; D. Rus, USGS / NE Water Science Center; S.C. Fisher, USGS / New York Water Science Center; D. Fairbairn, Minnesota Pollution Control Agency; J. Jaeschke, A. Brennan, K. Hopkins, USGS*

Stormwater runoff in urban areas can contain a variety of chemical constituents, including contaminants of emerging concern (CECs) (e.g. pharmaceuticals, new-use pesticides, hormones, plasticizers, fire-retardants, fragrances, and personal-care products), that enter into surface waterbodies and infiltrate to groundwater. CECs are present in water resources on a global scale with mounting evidence of potential deleterious effects to both aquatic and terrestrial organisms. Green infrastructure (GI) is an emerging technology that is intended to supplement natural environmental processes with engineered systems to enhance stormwater infiltration into the subsurface. Municipalities and water management agencies across the United States are increasingly using GI at various scales to recharge groundwater, reduce stormwater volumes, and minimize contaminant loads to receiving surface waterbodies. Additional research is needed to provide accurate information on the chemical compositions and concentrations of CECs, and potential water-quality effects on groundwater from infiltration of stormwater using GI. As part of a national-scale study to determine the chemical compositions and concentrations of trace organic and inorganic chemicals in urban stormwater from a range of watershed sizes and landuses, 57 stormwater samples were collected from 21 field sites across 17 states. Targeted chemicals included 476 trace organics (e.g. halogenated chemicals, hormones, halogenated chemicals, methylmercury, pharmaceuticals, pesticides,) and 64 inorganic (e.g. anions, cations, total mercury, trace and rare-earth elements) constituents. Stormwater samples were collected before flowing into surface waterbodies or infiltration to groundwater via GI (e.g. rain gardens, ecological recharge basins, spreading grounds). Preliminary results indicate that organic chemicals are ubiquitous in urban stormwater. Watershed characteristics (e.g. topography, landuse, climate, geology, etc.) and storm event hydrology will be used to interpret the complete set of chemical data.

**649 Nontarget screening for organic contaminants in wastewater at a sub-sewershed scale to identify spatial and temporal patterns**

*M. Hattaway, University of California, Davis / Civil and Environmental Engineering; J. Teerlink, California Department of Pesticide Regulation / Surface Water Protection Program; C. Alaimo, University of California, Davis; T.M. Young, University of California, Davis / Civil and Environmental Engineering*

Trace organic constituents (TOCs) such as pesticides and pharmaceuticals have been identified in wastewater entering treatment facilities, creating concern due to their poor removal by conventional wastewater treatment and toxicity potential in receiving environmental waters. However, there is little source information for these TOCs on a sub-sewershed scale. This study examines 24-h time-weighted composite samples collected monthly from February through December of 2016, at the wastewater treatment plant influent, effluent, ten sub-sewershed laterals, and three locations expected to have high pesticide loads (i.e. pet groomer, pest control operator, and laundromat). All samples were analyzed using both liquid and gas chromatography time-of-flight mass spectrometry (LC-QTOF-MS and GC-QTOF-MS) to comprehensively screen for roughly 3500 suspect chemicals. LC-QTOF-MS data were acquired using electrospray ionization (ESI) in positive and negative modes with All-Ions fragmentation, and two accurate mass MS/MS libraries containing >2000 chemicals were screened. The extracts were run on GC-QTOF-MS in electron impact (EI) mode using a retention time locked method and the spectra were screened against a pesticide library containing exact mass fragments and retention times. This study focusses on both the ways in which TOCs in the sewershed vary with time and space, and the contributions of residential, industrial, commercial, institutional, and municipal sources.

**650 Occurrence and Sources of Pesticides to Urban Wastewater and the Environment**

*J. Teerlink, California Department of Pesticide Regulation / Surface Water Protection Program; K. Moran, TDC Environmental, LLC; Y. Xie, California Department of Pesticide Regulation; R. Budd, Cal EPA / Dept. of Pesticide Regulation; D. Lin, San Francisco Estuary Institute / Department of Civil and Environmental Engineering; R. Sutton, San Francisco Estuary Institute*

Municipal wastewater has long been recognized as a pathway for discharge to receiving waters and the environment of contaminants derived from pharmaceuticals, personal care and cleaning formulations, and other consumer products. However, relatively few studies have evaluated this pathway for current-use pesticides. A state-of-the-science overview of the occurrence and fate of pesticides in wastewater, both before and after treatment, indicates this pathway is significant and should not be overlooked. A comprehensive conceptual model will be presented to establish all relevant pesticide use patterns with the potential for down-the-drain transport, both through direct wash-off and indirect contact resulting in subsequent wash-off. Case studies will highlight the importance of neglected sources of environmental contamination via the wastewater pathway. Recommendations for future monitoring and modeling studies to inform source control will be provided based on analysis of key data gaps.

**651 Estimating environmental emissions and aquatic fate of sludge-bound CECs using spatial modeling and US datasets**

*C.M. Holmes, Waterborne Environmental, Inc.; J. Amos, Waterborne Environmental, Inc. / Geospatial Data Technologies; A. Ritter, W.M. Williams, Waterborne Environmental, Inc.*

In the US, 50% of the sludge produced during wastewater treatment is recycled to land (www.epa.gov/biosolids). Some chemicals in consumer products may be highly removed during the wastewater treatment process due to sorption and binding to organic matter, ending up in sludge solids where it has the potential to be applied to land surfaces, subject to erosion or runoff processes potentially entering nearby surface waters. However, biosolids mass applied to land is not evenly distributed across the US landscape due to variable population density, local sludge management practices, and availability of land application sites. We have developed a proof-of-concept model to aide in the prospective assessment of CECs contained in WWTP sludge applied to land. This spatially-explicit, national model is based on publicly available datasets, combined with a spatial-hydrologic framework containing geographically variable emissions linked to a river network allowing for environmental transport via surface water. The hydrologic framework is based on a set of basins and rivers (www.hydrosheds.org) linked to emission characteristics for over 77,000 sub-basins. Emission characteristics are derived from facility data in the USEPA Clean Watersheds Needs Survey (www.epa.gov/cwns) to estimate consumer product usage linked to wastewater treatment, and spatially-variable data on biosolid applications. The USDA Cropland Data Layer (www.nass.usda.gov) provides potential land application sites, from which proximity to surface water plays a role in the potential for CECs to transport from land to freshwater (using a meta-model estimated from pesticide assessment models). Concentrations of CECs are routed through the river network based on local river attributes (e.g., flow) combined with assumptions about chemical fate in the aquatic environment. Results of various simulations show the spatial patterns of biosolids applications, potential to enter surface water, and estimated freshwater concentrations of an ingredient in a hypothetical consumer product. Implications of altering model assumptions are discussed. While the presented material is a simulated example of the environmental emission and fate of a consumer product ingredient, it represents a viable approach to assessing whether this pathway via land applied biosolids may be of concern for consumer product chemicals, and ultimately helping to inform environmental policy on this subject.

**652 Environmental Conditions Affecting Re-release of 4-Nonylphenol into an Aqueous Medium**

*R. Lyons, University of Redlands / Chemistry*

4-Nonylphenol (4NP) is a persistent organic pollutant with endocrine disrupting properties. This non-polar product of microbial degradation is derived from the surfactant nonylphenol polyethoxylate (NPE). 4NP is capable of long range transport from its point of application. The Sierra Nevada Mountains (SNM) divide the agricultural Central Valley from the pristine eastern slopes. Bioactive concentrations of 4NP have been found in the surface water, soils, snow and particulate matter of the Eastern SNM. Seasonal snow pack concentrations can be 20 to 100 times higher than in surface waters, and 4NP was detected in snow samples from the Palisade Glacier. Accelerated glacial ablation may result in a significant release of 4NP from particulates in glacial melt water. To determine whether 4NP will re-release from particulates into glacial melt water, batch desorption assays were run on particulate matter dosed with 4NP. Desorption was measured in 63, 125, 250 and 500 mm particles under two different temperature conditions and with varying fractions of organic carbon (OC). Water turbulence effects on the fraction of 4NP released were also investigated. Lower temperature slowed the release rate of 4NP from particulates, but at equilibrium the amount released was statistically the same. Similarly, turbulence has little effect on the total percent of 4NP released. There was a statistically significant correlation ($r = 0.72$) between the percent of organic carbon in the particulate matter and the concentration of bound 4NP found in environmental samples. However, particulates with higher percentages OC (80% or more) released very little of the bound 4NP (0.003%) compared to particulates containing 4-5% OC, which released up to 15%. Particle size had the most significant effect on the release of 4NP. Smaller particles (< 63 mm) released up to 35% of bound 4NP, all other things being held constant, versus particles 500 mm or larger, which may release as little as 0.1 to 1%. This may be attributable to surface adsorption in smaller particles versus surface and pore space absorption in larger particles. Glacial flour, the fine particles created as glaciers grind rocks to powder, can be smaller than 1 mm in size. Water and sediment samples taken from below the Palisades Glacier showed the greatest 4NP concentrations at the lakes directly below the glacier. This implies that glacial flour is likely to release a high percentage of any adsorbed 4NP.

## Water and Land Management to Reduce Methylmercury Bioaccumulation

### 653 Effect of organic matter concentration and characteristics on mercury mobilization and methylmercury production at an abandoned mine site

*C. Eckley, USEPA Region 10; T.P. Luxton, USEPA / Land and Materials Management Division; B. Stanfield, USEPA Region X; A. Baldwin, USGS / Idaho Water Science Center; J. Holloway, USGS; J. McKernan, USEPA; B. Poulin, USGS; M.S. Johnson, US Army Public Health Center / Toxicology*

Thousands of abandoned mines throughout the western region of North America contain elevated total-mercury (THg) concentrations. Soil amendments that promote vegetation growth on mine tailing may reduce erosion of high Hg content particles that can be transported to downstream waterbodies. Many of the mine sites exhibit minimal vegetative cover due to a lack of nutrients and organic carbon in the tailings and are susceptible to erosion. Application of organic soil amendments is a proven technique to promote vegetation growth on mine tailings and reduce erosion. However, in the case of Hg, organic matter additions have the potential to exacerbate Hg contamination by simulating microbial populations capable of producing the more toxic and bioaccumulative organic form of Hg (methylmercury—MeHg). The project's objectives were: 1) determine the mechanism by which Hg is mobilized from an abandoned mine site (Cinnabar Mine, ID), and 2) identify how variations in organic matter additions and quality (assessed through excitation emission matrix fluorescence spectroscopy —EEMs) affect MeHg production in mine tailings. Annual loads of filtered-passing and particulate THg at a downstream gaging station were modeled using LOADEST (n=34). To assess MeHg production, stable isotope methylation assays and mesocosm experiments were conducted using different types of commercially available organic matter soil amendments to mine tailings. The results showed that >80% of the THg mobilized from the mine was bound to particles and >90% of the annual loading occurred during the period of elevated discharge during spring snowmelt. Methylation rates varied between different types of soil amendments and were the most strongly correlated with the EEMs T and N peaks. The mesocosm experiments showed that under anoxic conditions carbon amendments to tailings could significantly increase porewater MeHg concentrations (up to 13 ±3 ng/L). In addition, the carbon amendments significantly increased THg partitioning to the porewater. Overall, these results indicate that efforts to reduce surface erosion at abandoned mine sites could be effective at reducing Hg mobilization with particles to downstream waterbodies; however, some types of soil amendments have the potential to significantly increase Hg methylation as well as THg partitioning to porewater.

### 654 In-situ coagulation systems can lower wetland mercury export and bioaccumulation

*J. Fleck, USGS / California Water Science Center; E. De Parsia, T. Kraus, USGS / CAWSC; J.T. Ackerman, USGS / Western Ecological Research Center; E. Stumpner, USGS / CAWSC; D.P. Krabbenhoft, USGS; M. Marvin-DiPasquale, USGS / Water Mission Area; C.N. Alpers, USGS / California Water Science Center; P. Bachand, Bachand and Associates*

Coagulation is commonly used to remove constituents from water, including dissolved organic matter (DOM) and suspended particulate matter (SPM), via the formation of larger particles (flocculate, or floc) which settle out of the water column. Because mercury (Hg) and methylmercury (MeHg) are predominantly bound to DOM and SPM, coagulation may be effective in controlling their fate and transport. In a series of Hg-related studies, our USGS team demonstrated that additions of metallic and chitosan-based coagulants to a variety of surface waters promotes removal of Hg and MeHg. Laboratory studies showed that coagulation effectively traps Hg and MeHg associated with DOM and fine, suspended particulates in larger aggregates and (or) denser particulate forms that settle out. Once deposited, the sedimentary materials largely remain intact and are relatively stable. Field-based studies conducted in the Sacramento-San Joaquin Delta and the Cache Creek watershed confirmed the overall effectiveness of Fe- and Al-based coagulants for removal of Hg and MeHg from both DOM- and particle-bound Hg species, whereas chitosan-based coagulants were effective for the removal of Hg and MeHg adsorbed to SPM only. Stability studies following deposition showed that a portion of the Hg in the settled floc was subsequently released under anaerobic conditions, whereas under aerobic conditions, Hg and MeHg were released into the dissolved phase as floc degraded. THg concentrations in the overlying water were higher for the Fe-based treatment than for the Al-based treatment and the (untreated) control, but the converse was true for MeHg because new MeHg production was inhibited by the Fe-based treatment. The Al-based treatment produced larger and more physically stable flocs than either Fe-based or chitosan-based treatment. Overall, less than 5% of THg and MeHg removed via coagulation and settling was subsequent released from settled materials under the conditions tested. Furthermore, the Fe-based treatment was more effective than the Al-based treatment for decreasing Hg bioaccumulation in fish. In general, coagulation was broadly effective for transferring Hg and MeHg from water to sediment, and treated wetlands show a net benefit for minimizing THg and MeHg transport (relative to control wetlands). Overall, Fe-based treatments appear to be more effective at reducing water-column Hg concentrations and bioaccumulation than Al-based treatments.

### 655 Seasonal and Redox-Mediated Patterns of Methylmercury Release from Profundal Sediment in Hodges Reservoir, California

*M. Beutel, University of California, Merced / Civil and Environmental Engineering; B. Fuhrmann, University of California, Merced; S. Brower, J. Pasek, City of San Diego Public Utilities Department; P. O'Day, University of California, Merced*

The San Diego Public Utilities Department will install an 8-ton per day hypolimnetic oxygenation system to enhance bottom water quality in Hodges Reservoir, a hypereutrophic reservoir near San Diego, California. The primary aim of the oxygenation system is to lower internal nutrient loading. But with the implementation of the State Water Board's Statewide Mercury Control Program for Reservoirs, there is also interest in assessing if oxygenation will repress the buildup of toxic methylmercury (MeHg) in anoxic bottom water. We implemented a laboratory and field monitoring effort to assess nutrient and metal cycling in the profundal zone under differing redox regimes. Replicate bench-scale sediment-water interface chambers (~2 L) containing profundal sediment were incubated under oxic and anoxic conditions. Chamber water overlaying sediment was monitored for several redox-sensitive parameters including MeHg, phosphate, ammonia, manganese, and sulfide. In general, maintenance of a well-oxygenated sediment-water interface repressed sediment release of these compounds. Typical oxic and anoxic fluxes were < 5 versus 20-40 mg-P/m$^2$·d for phosphate, < 5 versus 60-140 mg-N/m$^2$·d for ammonia, < 1 versus 50-60 mg/m$^2$·d for manganese, and < 20 versus 150-300 ng/m$^2$·d for MeHg. Sulfate uptake positively correlated ($R^2 = 0.62$, $P < 0.02$, n = 8) with MeHg efflux in chambers early in the anoxic phase, but not in the late anoxic phase when MeHg efflux dropped dramatically. This drop may be attributed to a decrease in Hg(II) bioavailability associated with sulfidic conditions or enhanced demethylation associated with methanogenesis. At the field scale, water quality monitoring in 2017 mirrored experimental results. Bottom water anoxia was associated with hypolimnetic buildup of redox sensitive compounds. Buildup of MeHg (~1 ng/L) in bottom water showed a seasonal cycle, increasing in the summer but then decreasing in the early fall, coincidental with significant sulfide accumulation (~ 25 mg/L). Both experimental results and field monitoring suggest that in eutrophic reservoirs, there is an early seasonal window of moderately reduced redox that is optimal for MeHg production in the profundal zone. Results also suggest that incomplete oxygenation of the profundal zone could inadvertently enhance MeHg buildup by shifting the profundal zone from highly reduced conditions to mildly reduced conditions that favor MeHg production.

**656 Mercury bioaccumulation through a semi-arid river-reservoir system: Effects of reservoir structure and habitat type**

*C. Eagles-Smith, J.J. Willacker, USGS / Forest and Rangeland Ecosystem Science Center; D.P. Krabbenhoft, USGS; S. Janssen, USGS / Wisconsin Water Science Center / Environmental Science; M. Tate, USGS; J. Naymick, J. Chandler, Idaho Power Company*

Hydrologic alteration is a defining ecological stressor to aquatic habitats associated with the Anthropocene, particularly in arid environments. Reservoir creation and subsequent management can have substantial influences on water quality, food web structure, and habitat availability. Additionally, reservoir creation has been shown to increase methylmercury production and bioaccumulation in newly inundated systems. However, relatively less is known about mercury bioaccumulation in established reservoirs or in contrast with other aquatic habitats. Paring studies at two different scales, we evaluated how Hg bioaccumulation varies among habitats and through reservoir food webs. First, we examined differences in fish mercury concentrations between free-flowing and impounded segments of the Snake River in Idaho, USA, a semi-arid river with 22 impoundments constructed between the early 1900's and 1980's along its course. Next, in a three-reservoir complex within the system we examined spatial and temporal variation of mercury transfer through the food web, and used mercury isotopes to examine potential source attribution. Along the Snake River, preliminary results indicate that fish mercury concentrations in reservoirs (0.141 ± 0.003 µg/g ww) and river segments directly below reservoirs (0.143 ± 0.005 µg/g ww) are 1.7- and 1.8-fold higher, respectively than in free-flowing segments not directly below reservoirs (0.082 ± 0.003 µg/g ww). Further, in free-flowing river segments, bass THg concentrations declined with distance from the nearest upstream dam, suggesting that these reservoirs can influence mercury bioaccumulation in fishes far downstream. Within reservoirs, methylmercury concentrations at the base of the food web were 2.3-fold higher at stratified locations in comparison to oxygenated, mixed habitats. Additionally, small prey fish mercury concentrations closely matched the spatial patterns of lower food web organisms, whereas top predator fishes increased by 3.3-fold through the linear extent of the complex. Cumulatively, our findings are indicate that reservoirs play an important role in mercury risk of aquatic ecosystems, but as highly managed habtats may also provide unique opportunities to mitigate this risk.

**657 Implications of freshwater mussels on mercury cycling and bioaccumulation in fish**

*T. Mathews, Oak Ridge National Laboratory / Environmental Sciences Division; A. Hills, R. McManamay, Oak Ridge National Laboratory*

Mercury is a globally important contaminant which is of particular concern in stream systems. Because the consumption of contaminated fish is the most significant source of mercury (Hg) exposure to humans, regulatory guidelines that focus on the protection of human health require monitoring of both aqueous and fish tissue Hg concentrations at contaminated sites. However, because Hg is predominantly accumulated in fish via dietary rather than aqueous exposure, the link between aqueous Hg concentrations and concentrations in fish is not always straightforward, confounding remediation efforts at contaminated sites. Benthic macroinvertebrates can often comprise a major portion of fish diets and can therefore be important in the trophic transfer of bioaccumulative contaminants like Hg to fish. In particular, freshwater mussels, because they filter particulates (and dissolved nutrients) from the water column, can affect mercury bioaccumulation throughout the food web by exerting effects on periphyton, dissolved organic matter, methylating bacteria, and dissolved mercury concentrations. The conservation of mussel populations is increasingly recognized to be a critical need, because they are among the most threatened group of organisms globally and because they are keystone species in riverine systems, providing multiple ecosystem services. Here, we examine the potential implications of re-introducing native freshwater mussels into East Fork Poplar Creek, a Hg-contaminated stream in East Tennessee. We combine results from laboratory experiments and field deployments to quantify filtration and mercury uptake rates in four species of mussels (Utterbackia imbecillis, Villosa iris, Lampsilis ovata, and Lampsilis fasciola) under varying environmental conditions and model effects on mercury bioaccumulation in fish. Our results indicate that filtration by freshwater mussels can have a significant impact on mercury concentrations and bioaccumulation in stream food webs.

**658 Quantifying the effects of activated carbon amendment and tidal inundation on mercury and methylmercury partitioning in Phragmites marsh mesocosms**

*G. Schwartz, Oak Ridge National Laboratory / Environmental Sciences; T. Bell, A. McBurney, Smithsonian Environmental Research Center; D. Vlassopoulos, Anchor QEA, LLC; S.S. Brown, The Dow Chemical Company / Environmental Remediation and Restoration; C. Gilmour, Smithsonian Environmental Research Center*

Activated carbon (AC) has been proposed as an in situ remediation method for mercury (Hg) and methylmercury (MeHg) in ecologically sensitive environments. A limited set of field trials and laboratory experiments have shown that AC amendments increase the partitioning of Hg and MeHg to the solid phase, decreasing porewater concentrations and bioaccumulation in benthic organisms. However, available data also suggest that AC efficacy varies with site geochemistry, and more data are needed to determine which environmental parameters dictate AC efficacy. With this study, we used field mesocosms to investigate the effectiveness of AC as an in situ amendment in Hg and MeHg-contaminated soil from the Berry's Creek wetland in New Jersey, USA. The objectives of this study were to: (1) assess the impact of AC on MeHg and Hg concentrations in porewater in *Phragmites* marsh mesocosms; (2) to evaluate the impact of tidal elevation on the efficacy of the AC amendment; and (3) to determine the impact of AC on Hg and MeHg partitioning into the solid phase. *Phragmites* marsh mesocosms were constructed from large-diameter, capped, PVC pipes and set at two different elevations in a tidal creek. Three types of treatment mesocosms were constructed: Control, 5% dw AC-amended, and 9 % dw AC+$MnO_2$-amended. The $MnO_2$ was added to poise redox potential at manganese reduction. Mn(IV) is a more energetically favorable electron accepter for bacteria than iron or sulfate, and an excess of Mn(IV) could shift the microbial community away from sulfate and iron reduction, reducing the population of Hg-methylating bacteria. Mesocosm porewater was monitored over four months. Sediment cores were taken at the conclusion of the experiment. The 9% AC+$MnO_2$ treatment decreased porewater Hg by ~85% and MeHg ~75X% relative to controls, while the 5% AC treatment decreased Hg by ~40%, and MeHg by ~25% (the latter was not a significant reduction). Mesocosm elevation significantly impacted redox chemistry in porewater and soil, but no significant difference was seen in Hg and MeHg porewater concentrations. Both the 5% AC and 9% AC+$MnO_2$ treatments significantly increased Hg and MeHg partitioning to soils. There was no significant difference between treatments for soil Hg concentration, but both amendments significantly increased soil MeHg concentration. These results contribute to our overall goal to develop an empirical model to predict the efficacy of AC for Hg and MeHg remediation across ecosystems.

**659 Investigations on the sources of Yolo Bypass floodwater methylmercury production**

*C. DiGiorgio, State of California / Department of Water Resources; M. Stephenson, W. Heim, California State University / Moss Landing Marine Laboratories; G.A. Gill, Pacific Northwest National Laboratory / Marine Sciences Laboratory; D. Bosworth, State of California / Department of Water Resources; R. Harris, Reed Harris Environmental Ltd.; P. Work, D. Schoellhamer, USGS*

The State of California, Central Valley Regional Water Quality Control Board (Board), adopted amendments to its Basin Plan in 2010 to address mercury (Hg) and methylmercury (MeHg) impairment in the Sacramento-San Joaquin Delta (Delta), the largest estuary on the west coast. Previous studies have demonstrated that in some months the Sacramento River contributes between 50 and 85 percent of the MeHg to

the Delta. However, during major flood events, the Yolo Bypass produces approximately 40% of all MeHg exported from the Sacramento basin. This is surprising because the Yolo Bypass, a 59,000-acre flood conveyance system designed to divert Sacramento River storm water around the City of Sacramento, is 285 times smaller than the 16,765,000 acre Sacramento Basin. The Board is requiring that total MeHg loads from the Yolo Bypass be reduced from 100 g/yr to 22 g/yr, a 78% reduction. The State of California, Department of Water Resources (DWR) is required to evaluate whether operational changes or other management strategies could be implemented to reduce open water MeHg production. As part of this mandate, DWR, together with collaborating agencies, are investigating if Best Management Practices (BMPs) are available to mitigate MeHg export from the Yolo Bypass. However, BMP recommendations require an understanding of the dominant sources contributing to the observed MeHg in-bypass production. This presentation focuses on a series of laboratory, mesocosm, and field studies investigating the relative contributions of erosion, pore water flux, and senescing vegetation inundated by flood waters to in-bypass production. Our scaled-up load calculations from different land uses for erosion and pore water flux suggests that while these sources may be important contributors to MeHg load under small and localized flooding events, they cannot account for observed in-bypass production under the large flooding events associated with export of MeHg from the Yolo Bypass. Since pasture lands are the largest land use in the Yolo Bypass, our investigations are focusing on the role vegetation could play in-bypass production. Our flooded mesocosm pilot experiments, incubated for 35 days under ambient winter conditions, showed that MeHg production differed significantly between disked and vegetated Yolo Bypass pasture lands. Follow-up experiments are in the design stage to further refine whether vegetation reduction can be used as a BMP to limit MeHg production in the Yolo Bypass.

**660 Importance of habitat to methylmercury distribution in water, sediment, and biota in a managed floodplain, Northern California**

*C.N. Alpers, USGS / California Water Science Center; M. Marvin-DiPasquale, L. Windham-Myers, USGS / Water Mission Area; J.T. Ackerman, USGS / Western Ecological Research Center; J. Fleck, USGS / California Water Science Center; C.A. Stricker, USGS / Fort Collins Science Center; K. Brown, California Department of Water Resources*

The Cache Creek Settling Basin (CCSB) is a 1600-hectare floodplain area in Yolo County, California (USA) bounded by levees since its construction in 1937 and expansion in 1993. The CCSB traps sediment to reduce deposition in the Yolo Bypass, a conveyance for Sacramento River flood waters, that protects the city of Sacramento. The CCSB traps particulate mercury (Hg) from the Cache Creek watershed, which has several natural and anthropogenic Hg sources: wastes from inactive Hg mines and gold mines (where Hg-amalgamation was used historically), mineral springs, and erosion of geologic materials with naturally elevated Hg. Load calculations based on water sampling during 2010–15 indicate: 62% ± 7% of particulate total Hg (THg) was trapped in the CCSB, with no net change in filtered-water THg load; 60% ± 10% of particulate methylmercury (MeHg) was trapped, whereas filtered-water MeHg load increased 38% ± 26% in basin outflows relative to inflows. To investigate MeHg gradients within the CCSB, four principal habitats were mapped: open water (stream channels and canals), riparian (along stream channels), non-agricultural floodplain, and agricultural (row crops, primarily corn and tomato). In shallow sediment (0–2 cm) collected at 93 locations within the CCSB during 2010–17, agricultural and open-water habitats had consistently lower MeHg than riparian and non-agricultural floodplain habitats, and lower total reduced sulfur (TRS) and organic matter. Within each habitat, there was an increase along the direction of stream flow in sediment %MeHg (100*MeHg/THg). TRS and organic matter also increased in the flow direction, and median grain size decreased. THg in tissue of western mosquitofish (Gambusia affinis), for caged (30-day exposure) and wild samples, and in water samples collected at the fish-cage sites also increased with downstream distance. THg in house wren (Troglodytes aedon) eggs increased with downstream distance during the wetter years but not the drier years of the study. Sediment MeHg was higher when the basin was flooded, whereas reactive Hg(II), a precursor to MeHg, was higher during drier periods. The finding that riparian and non-agricultural floodplain habitats had significantly higher %MeHg than agricultural (row-crop) and open-water habitats (by a factor of about 2) could have broad implications for resource management, given that these habitats are typical of managed floodplains in California and elsewhere.

## Soil Contaminants: Fate, Bioavailability, Environmental Toxicology in Ecological and Human Health Risk Assessment

**661 Recommendations for Sieving Soil and Dust Samples at Superfund Sites for Assessment of Incidental Ingestion Exposures**

*M. Stifelman, USEPA Region 10; M. Follansbee, SRC, Inc. / Environmental Health Assessment; J.B. Brown, Faculty of LBNL / Molecular Ecosystems Biology; G. Diamond, SRC, Inc. / Environmental Health Assessment; M. Burgess, USEPA / OSRTI; Y. Lowney, Alloy, LLC / Health Sciences*

Recommendations for sieving soil and dust samples at Superfund sites for assessment of incidental ingestion via dermal adherence Incidental ingestion is the primary pathway for exposure to lead, and other contaminants, in soil and dust. The current understanding of this exposure pathway assumes that incidental ingestion occurs subsequent to (and is dependent on) dermal adherence. Hence, site-specific risk assessment requires that soil and dust samples be sieved to accurately represent incidentally ingested material that adheres to skin. Reliable data on the particle size fraction that is most likely to adhere to hands, and on the lead concentration found in that particle size, can improve the accuracy of exposure and risk calculations in lead risk assessments. In response to this data need, the EPA has prepared guidance for sieving soil and dust samples for assessment of incidental ingestion. The focus of the guidance is on lead-contaminated sites, but is also applicable to assessments of exposure to other contaminants in soil or dust. The guidance document contains a review of the current data on the relationship between particle size fractions sieved at lead-contaminated sites and the likelihood that they will adhere to hands and be incidentally ingested. The existing sieving guidance, developed by EPA's Office of Land and Emergency Management (OLEM) in 1994, recommended the

**662 Bioavailability of Arsenic in Surface Soil from Historical Herbicide Application**

*K.M. Henry, Tetra Tech EM, Inc. / School of Life Sciences; J. Canepa, Tetra Tech, Inc.*

Determining a site-specific relative bioavailability (RBA) value for a chemical in soil allows for the development of a site-specific risk-based remedial goal that is protective of human health but not unnecessarily conservative. An assessment of the RBA of arsenic in surface soil was conducted for a site in northern California impacted by historical application of arsenical herbicides. Detected concentrations of arsenic at the site range from below the background level of 10 milligrams per kilogram (mg/kg) to 240 mg/kg and a human health risk assessment indicated arsenic in surface soil (0-0.5 foot) poses a risk to future residential receptors. This bioavailability study, conducted prior to the recent releases of state and federal guidance for in vitro testing, included paired in vivo (swine) and in vitro tests to identify the method(s) appropriate for further in vitro testing of additional samples. Relatively low variation in the predicted RBA was reported for thirty-seven soil samples collected from locations throughout the site with arsenic concentrations that ranged nearly two orders of magnitude in concentration (from 1.97 to 164 mg/kg). A site-specific RBA of 39.5 percent was selected based on the in vivo tests, the results of which were similar to the sitewide in vitro tests.

**663 California Arsenic Bioaccessibility Method: Recommended Method for bench-Top Prediction of Relative Bioavailability in Contaminated Soils**

*V. Hanley, Cal. EPA / DTSC; S. Whitacre, The Ohio State University; C. Sorrentino, California Department of Toxic Substances Control; N.T. Basta, The Ohio State University / School of Environment and Natural Resources*

The California Department of Toxic Substances Control (DTSC) Human and Ecological Risk Office (HERO) recently released guidance on evaluating arsenic bioavailability in contaminated soils. Human Health Risk Assessment (HHRA) Note 6 recommends using the recently published California Arsenic Bioaccessibility (CAB) in vitro method to predict in vivo relative bioavailability (RBA). Traditional HHRAs assume that arsenic in soils is 100% bioavailable. However, it is well known that this is not typically the case; USEPA recommends a default RBA of 60% in the absence of site-specific data. Until recently this meant using an in vivo animal study, which are both expensive and time consuming. CAB is a quick and inexpensive method, which allows for a more efficient use of the resources available for the cleanup while maintaining a high level of health protectiveness. CAB is highly predictive of arsenic RBAs for a wide variety of soil types when the total arsenic concentrations are less than 1,500 mg/kg, but tends to over-predict in soils with higher levels of arsenic. Consequently, DTSC is recommending the use of CAB to predict site-specific RBAs of arsenic in soil at most sites under its jurisdiction. HHRA Note 6 provides guidance on when and where it is most advantageous to conduct a bioavailability study using CAB and how the results of such a study should be incorporated into a risk assessment. Important considerations include the naturally occurring background concentrations of arsenic, the range of arsenic due to contamination, the planned future land use of the site, and community acceptance. Risk-based concentrations for arsenic are typically lower than naturally occurring background levels in soils. HHRA Note 6 provides guidance on how to determine clean-up values under multiple outcome scenarios. DTSC HERO toxicologists are available for consultation on applying this guidance on a site-specific basis and have a long-term goal of creating a database of all sites in the State that have used CAB in their decision making process. This database would be publically accessible with the goal of helping to inform future site evalutions.

**664 Predicting Arsenic Bioavailability in Contaminated Soils by Using In Vitro Gastrointestinal Bioaccessibility and Speciation**

*N.T. Basta, The Ohio State University / School of Environment and Natural Resources; B.N. Stevens, US Army Corps of Engineers / ERDC / Environmental Laboratory; K. Scheckel, USEPA; S. Whitacre, The Ohio State University; A. Betts, University of Delaware; V. Hanley, California Department of Toxic Substances Control*

Exposure risk associated with soils contaminated with As is assessed by human health risk assessment (HHRA). A more accurate and site-specific HHRA accounts for bioavailability of soil As. Extensive research efforts have been directed toward development and application of in vitro gastrointestinal methods to predict relative bioavailable As (RBA As) across four continents. RBA As vs. IVBA As regression equations are used to predict RBA from IVBA. These methods are gaining regulatory acceptance for HHRA on contaminated sites. However, the ability of bioaccessibility methods to predict RBA As for contaminated sites and sources outside those used in developing the IVIVC regression equation is unknown. The objective of the current study is to evaluate the ability of several international bioaccessibility methods to predict RBA As for 12 contaminated sites. Arsenic bioaccessibility, determined using five in vitro methods, ranged from < 1 to >90% for 27 arsenic contaminated soils. A variety of linear regression methods have been used throughout literature to produce in vivo-in vitro correlations (IVIVC). Subsequently, soils were collected from 12 contaminated sites (i.e., locations). Bioaccessible As (IVBA As) was determined by several in vitro gastro(intestinal) methods including the SBRC, RBALP, USEPA Method 9200, OSU IVG, and the California Bioaccessibility method (CAB). Relative bioavailable (RBA) As was determined from dosing trials using juvenile swine. Regression equations from published IVIVC were used to predict RBA As from in vitro arsenic bioaccessibility. In general, the five IVBA bioaccessibility methods were predictive of RBA As for arsenic contaminated soils and solid wastes. Results from this study show IVBA methods provide reliable estimates of RBA As for use by contaminated site managers. However, several of the IVBA methods underpredicted RBA As when applied to specific sites. Despite As(V) adsorbed to mineral surfaces being a major component of most soils (>50%), soils ranged from ~20-80% in IVBA As and widely ranged in RBA As. Arsenic speciation alone is not predictive of IVBA or RBA As. However, As speciation is very important to provide information on IVBA or RBA As results. Supplemental site data (i.e., arsenic speciation) may be required for proper selection of methods by risk assessors to accurately predict RBA As and human exposure and gain acceptance by the regulatory community.

**665 Modeling the post-ingestion bioaccessibility of organic compounds sorbed to soils and house dusts**

*J. Starr, USEPA / National Exposure Research Laboratory; S. Haitao, Zhejiang Provincial Center for Disease Control and Prevention; W. Li, USEPA / National Exposure Reseach Laboratory; S. Graham, USEPA / Office of Air Quality Protection Standard*

Ingestion of soils and house dusts with sorbed toxicants is an important pathway for children's exposure to many regulated organic chemicals. Therefore, it is important to understand the extent to which soil/dust sorbed toxicants mobilize (become bioaccessible) in the digestive tract. We used an in vitro, three-compartment system to model the bioaccessibility of the insecticide fipronil and 18 polychlorinated biphenyls (PCBs) from 37 soil and 37 house dust samples. For each sample. freely dissolved and total concentrations of fipronil and PCBs in the digestive fluid were measured and compared to concentrations remaining in the soil/dust sediments to calculate percent free ($BA_{frc}$) and total ($BA_{totc}$) bioaccessible fractions. Physicochemical soil and dust properties, and log octanol-water partition coefficients (log $K_{ow}$) of fipronil and PCBs were used to generate bioaccessibility models. In soil, mean $BA_{totc}$ were 89 ± 10% (fipronil) and 65 ± 16 % (PCBs). In house dust, mean $BA_{totc}$ were 58 ± 17% (fipronil) and 36 ± 14 % (PCBs). Most of the bioaccessible fipronil was freely dissolved whereas all measurable PCBs were bound to organic constituents or trapped in micelles. The significant bioaccessibility predictors were: Carbon (fipronil soil, $r^2 = 0.62$; fipronil dust, $r^2 = 0.30$; PCBs soil $r^2 = 0.65$) and carbon/clay (PCBs dust, $r^2 = 0.56$). Combined fipronil / PCB models of $BA_{totc}$ retained only carbon and log $K_{ow}$ for both soil ($r^2 = 0.78$) and dust ($r^2 = 0.65$). These results indicate that bioaccessibility can be modeled using properties of chemicals, soils, and house dusts.

**666 Utility of Urinary Metabolites in the Design and Execution of In Vivo Bioavailability Studies of PAHs**

*B.H. Magee, ARCADIS; N.D. Forsberg, Arcadis U.S., Inc. / Environmental and Molecular Toxicology; G.C. Hoeger, Carollo Engineers / IEST; A.K. Meyer, US Army Corps of Engineers / Enivronmental and Munitions Center of Expertise*

Recent and ongoing bioavailability testing of PAHs in soils and from complex mixtures like coal tar, coal tar pitch, and soot has included in vivo bioavailability testing and in vitro bioaccessibility testing. Despite its cost, in vivo bioavailability test has a key role to play whether used for a site risk assessment or used to validate in vitro tests. Animal tests of noncarcinogenic PAHs, such as pyrene and phenanthrene, and potentially carcinogenic PAHs, such as benzo(a)pyrene (BaP), have been aptly summarized in detail by Ruby et al. (2016). These tests have used different dosimetrics, including urinary metabolites, circulating blood levels, PAH adduct levels, etc. No one approach has proved to be superior. A recent study that received regulatory approval in 2017 and was summarized as a case study in the Interstate Technology Regulatory Council (2017) guidance document entitled *Bioavailability of Contaminants in Soil: Considerations for Human Health Risk Assessment*, was presented at this meeting last year (Forsberg et al., 2017). This mouse study of soil containing coal tar pitch from clay pigeon fragments at DOD shotgun range sites successfully used water soluble hydroxylated PAH metabolites in the urine as the dosimetric. Because of the low fraction of ingested dose excreted in the urine as 3-OH and 9-OH BaP (0.5% for soil groups and 2% for soil extract groups), one must plan studies that use urinary metabolites with care. This paper will discuss the potential difficulties, specifically the need for low detection limits, the instability of de-conjugated hydroxy metabolites in mouse urine, and the potential for confounding by fecal contamination.

**667 Nutrient availability effects on wheat plant root exudate composition and exudate effects on sorption of lamotrigine to soil**

*E.L. Miller, University of Wisconsin – Madison / Molecular and Environmental Toxicology Center; S.M. Berg, University of Wisconsin Madison; S.L. Nason, Johns Hopkins University / Environmental Health and Engineering; K. Karthikeyan, University of Wisconsin, Madison / Biological Systems Engineering; C. Remucal, University of Wisconsin, Madison; J.A. Pedersen, University of Wisconsin, Madison / Soil Science*

Irrigation with treated wastewater and soil amendment with biosolids are increasingly common practices in agriculture, and result in crop plant exposure to a variety of ionizable organic contaminants (IOCs). Plants may take up and accumulate IOCs, but our understanding of the variables that control IOC phytoavailability contains many gaps, including limited understanding of processes occurring at the soil-plant interface. The rhizosphere, the 2-3 mm of soil immediately surrounding roots, can have significantly different properties than bulk soil. Plants release ions and organic compounds from their roots to maximize nutrient availability. These root exudates can result in significant changes to the pH and chemistry of the rhizosphere. Root exudates may also alter sorption of pollutants, changing bioavailability and biodegradation potential. However, little is known about how changes in nutrient availability can alter the composition of root exudates or how exudates may impact sorption of IOCs, thereby impacting IOC availability to plants. We grew hydroponic wheat plants in a variety of nutrient solution compositions and collected their root exudates. We then analyzed the exudates using UV-Vis spectroscopy and Fourier Transform – Ion Cyclotron Resonance Mass Spectrometry, and compared exudates from differing growth conditions. We also measured sorption of the cationic anti-epileptic drug lamotrigine to three field soils with and without the presence of root exudates. Soil organic carbon was the major driver of lamotrigine sorption, and root exudates altered sorption most in soils with low organic carbon. Implications of our results on the bioavailability and accumulation of other IOCs will be discussed.

**668 Ecological risk assessment of lead in soils: A complete dataset to allow bioavailability correction for direct toxicity and secondary poisoning**

*M.J. Chowdhury, International Lead Association; E.E. Smolders, KULeuven / Department of Earth Environmental Sciences; R.P. Lanno, Ohio State University / Department of Evolution, Ecology, and Organismal Biology; K. Oorts, ARCHE*

Metal bioavailability and toxicity in soil can be strongly affected by soil physico-chemical properties and ageing. In a multi-year study, the lead industry has addressed these issues with a view to analyzing terrestrial lead risk assessment. For direct toxicity, the study included measuring toxicity of lead (Pb) for 6 endpoints (2 plants, 2 invertebrates and 2 microbial endpoints) in a set of 7 soils covering a representative range of soil properties (pH, organic matter content, texture and eCEC). The effect of ageing was quantified by studying toxicity of Pb after 3 different contamination conditions: i) freshly spiked with $PbCl_2$, ii) freshly spiked, leached and pH corrected in order to remove salinity and pH stress, and iii) freshly spiked and aged for 5 years. Variation in soil properties significantly explained variation in Pb toxicity for some endpoints (e.g. nitrification), but not for other endpoints (e.g. microbial respiration, *Folsomia candida* reproduction). Leaching and long-term aging of soils attenuated Pb toxicity significantly with a median factor of 4.7, confirming higher toxicity in freshly spiked soils compared to soils equilibrated under field conditions. In a recent study for secondary poisoning, the effects of soil properties on biota-soil accumulation factors (BSAF) have been characterized for earthworm species and the risk of Pb is assessed for the food-chain soil => earthworms => earthworm eating predators (birds and mammals). The BSAF values (dry wt) identified as reliable are variable (0.01 to 22.05; median 0.23; n= 248) and no soil properties except eCEC are significantly ($P< 0.01$) correlated with BSAF. Several bioavailability models, developed relating soil properties to Pb toxicity or BSAF, allow normalization of soil toxicity data to site-specific soil properties. Considering a relevant range (approximately 10th-90th percentile) of soil eCEC, safe levels of Pb for direct toxicity vary between 150 and 450 mg Pb/kg, while for secondary poisoning between 120 and 400 mg Pb/kg. A computer interface for user-friendly uses of the above models together with species sensitivity distribution (SSD) analyses will be demonstrated in the context of implementing bioavailability for predicting ecological risks of Pb in soil for a given site.

## Protecting Freshwaters from Salinization

**669 The Salton Sea: A real-life experiment of extreme freshwater salinization**

*W.L. Goodfellow, Exponent, Inc. / Ecological and Biological Sciences Practice; A.M. Deines, Exponent, Inc / Ecological and Biological Services Practice*

The Salton Sea is California's largest lake, located in the Imperial and Coachella valleys. The waterbody is 35 miles long, 15 miles wide, and 236 ft below sea level, with water flow into the lake from the New, Whitewater, and Alamo Rivers, as well as agriculture run-off, drainage systems, and creeks. The waterbody is a closed system with no outflow. In 1905, flooding occurred within the Colorado River system, resulting in a breach of an Imperial Valley dike. Over approximately two years, nearly the entire river filled the Salton Sink, creating the Salton Sea. The newly created lake quickly became a tourist and recreational area, with many commercial enterprises, hotels, and resorts developed along the shoreline. The lake also became a frequent stop along the Pacific Flyway, with over 400 species documented at the Salton Sea including substantial populations of the American white pelican, long-billed curlew, white-faced ibis, and the mountain plover. From the early 1900s until present, the salinity of the waterbody has increased from 3 to approximately 60 ppt, roughly at a rate of 1–2 ppt or more per year; recent water transfers from the Imperial Valley have further accelerated the increase in salinity concentrations. Fish stocked in the heyday of the Salton Sea resort community first included primarily freshwater species such as the threadfin shad, common carp, red shiner, channel catfish, white catfish, largemouth bass, and the desert pupfish. As salinity increased, marine species dominated including Orangemouth corvina, Bairdiella, and sargo. Tilapia though typically considered freshwater species escaped from local aquaculture and now dominate the fish community. Currently the fish population is largely composed of Mozambique tilapia and its hybrid, with populations thought to be located at the many seeps, drains, and creeks entering the lake. This presentation will discuss the impacts to the lake fish population, including the ability of the cichlid species to tolerate the rapidly increasing salinity concentrations. Additionally, this paper will present Salton Sea management and restoration plans recently proposed by the California Natural Resource Agencies.

**670 Using simulated background waters and site waters that represent field conditions to investigate salt toxicity**

*A. Farag, USGS / CERC / Jackson Field Research Station; D. Harper, USGS / Columbia Environmental Research Center*

While it is important to use traditional laboratory waters (e.g. moderately hard reconstituted) to limit variability and allow for inter-laboratory comparisons of salt toxicity results, applied science in field waters where salinization may be occurring is critical to advance salt toxicity research. Site waters and/or laboratory waters prepared to simulate field chemistry are not only useful for site specific applications, but provide additional ground truthing for salt models, proposed management actions, and restoration efforts. This laboratory previously conducted a series of experiments of to investigate $NaHCO_3^-$ in the Powder River Basin, Wyoming where treatment options appeared to reduce toxicity. Similar methods are now being applied to NaCl toxicity in waters of North Dakota and Montana. The current research focuses on investigating the toxicity of NaCl under conditions where oil and gas flowback spills and legacy contamination have occurred among productive agricultural lands and wetlands. Concentrations of Ca are generally elevated in these waters, which may ameliorate salt toxicity. Duckweed (*Lemna gibba*) and *Daphnia* (*D. magna*) were exposed to both a background water simulating the Prairie Pothole Region of North Dakota with NaCl added, and to site water collected from Goose Lake, Montana. EC50s were smaller (by > 500 mg $Cl^-$ mg/L) for both species in the site water compared to the simulated water. The site water generally had 500 mg Ca/L more than the simulated background water and results indicate that the additional Ca did not provide protection against toxicity. Though Ca is known to ameliorate toxicity of salts at lesser concentrations, the threshold of protection is below what exists in field situations of North Dakota and eastern Montana. This finding is applicable for any flowback or receiving waters with elevated hardness concentrations. For both simulated water and site water, duckweed was more sensitive with lesser toxicity thresholds than *Daphnia* . A chronic toxicity experiment was performed with duckweed and preliminary results suggest that the chronic EC50 is approximately 1/3 that of the acute EC50 for the simulated Prairie and Pothole water. This documented sensitivity of duckweed is especially important as managers investigate restoration goals and options. The resilience of aquatic and semi-aquatic plants to salts is of particular concern for wetland and riparian habitats.

**671 Transepithelial Potential as a Metric of Major Ion Toxicity in Fish: 2. Salt Mixture Studies**

*K. Brix, EcoTox / Marine Biology and Ecology; M. McDonald, M. Grosell, University of Miami / Marine Biology and Ecology; D. Mount, USEPA / ORD / NHEERL / Mid-Continent Ecology Division-Duluth; W.J. Adams, Red Cap Consulting; C.M. Wood, University of British Columbia / Zoology*

Salinization of fresh waters is increasing on a world-wide basis and there is an urgent need to develop tools for regulating major ions in freshwater ecosystems. The multi-ion toxicity model has been developed over the last several years to meet this need. The model is based on a mechanistic framework where disturbance in transepithelial potential (TEP) at the gills is the physiological endpoint used to predict toxicity. The TEP is the electrical potential gradient across the branchial epithelium, and is a key factor both affecting, and affected by, the movement of major ions between the normally dilute external environment and the normally concentrated blood plasma. Its disturbance is associated with a disruption of normal ionoregulatory homeostasis. Here we present initial experiments using the channel catfish (*Ictalurus punctatus*) on the effects of binary salt mixtures on fish TEP. This represents a first test of whether TEP can predict the toxicity of salt mixtures. The fish were exposed separately to three binary salt combinations $MgSO_4$:$Na_2SO_4$, NaCl:$CaCl_2$, $MgCl_2$:KCl. After evaluating an isobologram approach based on traditional practice for mixture toxicity testing, we instead tested the effect of varying one salt while holding the other salt at several constant concentrations, and then conducted the reciprocal experiment. Each experiment evaluated 10-12 treatments across a range of concentrations that encompassed the 96-h LC50. The binary salt mixtures were selected as representative mixtures that elicit additive, independent and mixed toxicity based on acute toxicity data. Acute changes in TEP were measured using a high impedance voltmeter, and indwelling peritoneal catheters connected to silver chloride electrodes via KCL-agar bridges. Several ways of analyzing the data will be explored. Overall the results of these binary mixture salt tests reinforce the mechanistic basis for the TEP model for predicting major ion toxicity and suggest further testing with a broader diversity of species and a broader range of salt combinations is warranted to further evaluate the model.

**672 Sulfate toxicity in the mayfly *N. triangulifer*: Pumping ions is energetically taxing**

*D.B. Buchwalter, H. Chou, NC State University / Biological Sciences; S. Scheibener, NC State University; S. Westrud, University of North Carolina at Chapel Hill; M. Hoon, NC State University; J. Elphick, Nautilus Environmental*

Elevated major ion concentrations in streams are commonly observed as a consequence of resource extraction, de-icing and other anthropogenic activities. Ecologists report biodiversity losses associated with increasing salinity, with mayflies typically being highly responsive to increases of different major ions. In this study, we evaluated the performance of the mayfly *Neocloeon triangulifer* reared for its entire larval phase in a gradient of sulfate concentrations ranging from 0.058 to 15.6 mM $SO_4$. Water from two oligotrophic streams was amended with sulfate as a blend of $CaSO_4$ and $MgSO_4$ at a 2.4:1 mass ratio of Ca:Mg. Survival (percent successful emergence to the subimago stage) was significantly reduced at the highest $SO_4$ concentration in both waters, while elevated $SO_4$ significantly delayed development in both waters. Final sub-adult body weights were generally consistent across treatments, except at the highest treatment concentration, where adult size and fitness were compromised. Subimagos that emerged from these exposures spanning 4 orders of magnitude of $SO_4$ showed only very modest increases in whole body S concentrations, suggesting that these animals are strict osmo-regulators. Sulfate uptake in *N. triangulifer* is concentration dependent and follows typical Michaelis-Menten kinetics. However, even at extremely high environmental $SO_4$ concentrations, SO4 uptake continues to increase. Thus the cost of maintaining relatively stable body S when water $SO_4$ concentrations are elevated imposes an energetic demand that is manifested primarily as reduced growth rates and associated developmental delays. We are in the process of identifying genes related to sulfate transport in *N. triangulifer* and examining how their expression changes as a function of environmental salinity.

**673 Transepithelial Potential as a Metric of Major Ion Toxicity in Fish: 1. Single Salt Studies**

*C.M. Wood, University of British Columbia / Zoology; M. McDonald, M. Grosell, University of Miami / Marine Biology and Ecology; D. Mount, USEPA / ORD / NHEERL / Mid-Continent Ecology Division-Duluth; W.J. Adams, Red Cap Consulting; K. Brix, EcoTox / Marine Biology and Ecology*

As salinization of fresh waters is increasing on a world-wide basis, there is an urgent requirement to develop regulatory tools, and for such tools there is a need for an integrative metric of toxicity. Building on a developed modeling paradigm, we explore a mechanistic approach where the metric is disturbance of the transepithelial potential (TEP) at the gills. The TEP is the electrical potential gradient across the branchial epithelium, and is a key factor both affecting, and affected by, the movement of major ions between the normally dilute external environment and the normally concentrated blood plasma. Its disturbance is associated with a disruption of normal ionoregulatory homeostasis.The premise is that major ion toxicity can be predicted as a function of changes in TEP, with a given change in TEP associated with toxicity regardless of the major ion concentrations and composition needed to elicit that change. This TEP approach evolves from theoretical predictions of the depolarizing effects of major waterborne ions, which can be made if their relative branchial permeabilities and their blood and plasma concentrations are known. These predictions rely on the Goldman-Hodgkin-Katz and Spangler equations, which are extensions of the well-known Nernst equation. Here we present proof-of-principle experiments on three freshwater fish species (fathead minnow *Pimephales promelas*, channel catfish *Ictalurus punctatus*, and bluegill sunfish *Lepomis macrochirus*). The fish were exposed separately to 8 different salts (KCl, NaCl, $MgCl_2$, $CaCl_2$, $K_2SO_4$, $Na_2SO_4$, $MgSO_4$, $CaSO_4$) across a range of concentrations that encompassed the 96-h LC50. Acute changes in TEP were measured using a high impedance voltmeter, and indwelling peritoneal catheters connected to silver chloride electrodes via KCl-agar bridges. Several ways of analyzing the data will be explored.

Overall the results of these single salt tests indicate that while there are species-specific differences in the magnitude of responses, within each species, there is remarkable consistency between several TEP metrics and toxicity. These results reinforce the mechanistic basis for the TEP model for predicting major ion toxicity, and have encouraged us to now test the approach using binary salt mixtures.

**674 Predicting the Aquatic Toxicity of Mixtures of the Major Ions: Technical Update – Chronic Exposures and Additional Test Species**

Delos, Great Lakes Environmental Center; K.J. Farley, Manhattan College / Civil and Environmental Engineering; T. Lyons, HDR Inc.; P.R. Paquin, HDR / Water Quality Modeling; D.J. Soucek, Illinois Natural History Survey*

Elevated concentrations of mixtures of seven major ions ($Ca^{2+}$, $Mg^{2+}$, $Na^{+}$, $K^{+}$, $Cl^{-}$, $SO_4^{2-}$, and $HCO_3^{-}$) have become a concern in some freshwater systems. The development of water quality criteria for these constituents has proven to be a challenging endeavor because toxicity of any specific ion has been found to be influenced by both the total concentration of ions in the mixture and, importantly, mixture composition. Use of an integrative measure such as TDS or conductivity to evaluate multi-ion toxicity (MIT), provides an indication of the total ion concentration, but fails to address mixture composition. Because of the aforementioned limitations of relating aquatic toxicity to specific ion concentrations or TDS/conductivity, we have pursued the problem from a different perspective – by relating toxicity to trans-epithelial potential (TEP), a physiological parameter that is computed based on blood or hemolymph and external major ion concentrations and calibrated model parameter values. This approach has been successfully applied to a limited number of relatively large acute toxicity datasets (*C. dubia*, *D. magna*, *P. promelas* and *N. triangulifer*) with widely varying ion compositions and, more recently, to much smaller, less robust datasets for species that would ultimately be included in the species sensitivity distribution (SSD). This presentation reviews how the approach has been extended to additional small acute and chronic effects datasets with multiple species for the purpose of testing the existing approach as well as expanding it to additional organisms and exposure durations.

**675 The accumulation and effects of persistent-energy related brine contamination on amphibian populations**

*K.L. Smalling, USGS / NJ Water Science Center; B.R. Hossack, USGS; C.W. Anderson, USGS / Oregon Water Science Center; T. Preston, USGS; I.M. Cozzarelli, USGS / National Research Program; R.K. Honeycutt, USGS*

The Williston Basin overlaps the North America's Prairie Pothole Region, one of the world's largest prairies and wetland ecosystems. Oil and gas production in the Williston Basin has increased rapidly over the last 20 to 30 years and secondary salinization from wastewaters (brines) co-produced during energy production have the potential to affect freshwaters. These wastewaters contain elevated concentrations of sodium, chloride and other metals which can alter water quality, persist in wetland sediments and negatively affect organisms Amphibians are especially sensitive to salinization with the increased possibility of additive and synergistic interactions among other pollutants. Few studies have examined potential interactions between brines and metals that readily accumulate in sediments and tissues. There has also been little research on the population- or community-level effects of salinization from oil-related waste products on aquatic species. We sampled 33 wetlands in Montana and North Dakota for 3 amphibian species, and used N-mixture models (estimate of animal abundance from spatially replicated data) to determine how abundance varied with evidence of brine contamination. Mixed-effects linear models were also used to measure the association between metals in sediments and tissues, to determine if accumulation varied by species and feeding behaviors (grazer, leopard and chorus frog vs. predator, salamander). Abundance of boreal chorus frog larvae declined most rapidly in response to elevated chloride (range: 0.04–17500 mg/L), followed by the northern leopard frog and barred tiger salamander. Concentrations of several metals were correlated with differences in feeding habits (e.g., omnivorous grazers vs. predators) rather than brine contamination. These results suggest that closer contact with the bottom sediment (i.e. grazers) could lead to greater ingestion of metal-laden soils and result in higher concentrations in tissues, particularly for those metals with higher assimilation efficiencies. Our results reveal contamination from saline wastewaters are associated with population- and community-level effects on wetland amphibians but it is not clear whether these effects are caused solely by brines or if other pollutants are also playing a role. A more robust understanding of these complex systems would help land managers prioritize conservation, remediation and restoration efforts in wetlands affected by historic energy production.

**676 Development of risked-based water quality guidelines for the protection against secondary freshwater salinisation in South African freshwater**

*P.K. Mensah, Rhodes University / Institute for Water Research*

Freshwater salinisation in South Africa is on an increasing trajectory with elevated levels of sulphate, sodium and chloride ions in many of the country's rivers. This phenomenon is mainly from secondary sources, including salinity due to agriculture, mining and domestic wastewater effluent. Thus, the aim of this study was to develop risked-based water quality guidelines (WQGs) for the protection of freshwater resources in South Africa. Short term and long term lethal exposure tests were conducted with indigenous South African aquatic organisms belonging to different taxonomic groupings. Ecotoxicological experiments were conducted by exposing different species of organisms to either NaCl (representing agriculture source), $Na_2SO_4$ (representing mining source) and wastewater effluents, in separate experiments. Static non-renewal experimental methods were employed for short-term lethal tests ($\leq$ 96 h), and static renewal for long-term lethal tests (> 96 h $\leq$ 21 d). The mortality results were used to estimate the lethal concentration (LCx) values. The LCx values from these experiments, those from salt database hosted by the Institute for Water Research (IWR) and those from literature search were used to develop risk-based WQGs using the species sensitivity distribution (SSD) approach. Different median protective concentrations (PC) with their lower and upper predicted intervals were estimated for different proportions of the population against exposure to NaCl, $Na_2SO_4$ and wastewater effluents. The median protective concentrations of 95 % of the population (PC95) values of distributions together with their lower and upper predicted intervals are used as the WQGs. The PC95 value is the mean guideline, while the lower-upper predicted values represent acceptable limits, i.e., acceptable or tolerable risks. Beyond these, risks are unacceptable.

## Advancements in Green Infrastructure Systems Through Life Cycle Assessments

**677 Sustainability Assessment of Green Infrastructure: The case of Urban Farms and Food Systems in US and India**

*A. Ramaswami, University of Minnesota / Humphrey School of Public Affairs*

Cities worldwide are seeing an emergence of policies and actions that are promoting green infrastructure and urban food system policies (e.g., UN Habitat; Milan Food Pact), with the latter often focusing on programs that promote urban farming. Often, many and diverse benefits are attributed to local green infrastructures and urban food systems – including environmental resource sustainability, health benefits, equity benefits, flood and heat resilience, and wellbeing. However, the magnitude of these benefits are poorly quantified and also often contested. Systems approaches are needed to assess these diverse sustainability impacts and co-benefits. This talk will present results of multi-objective sustainability assessments of urban food systems in cities in US and India, with implications for design of green infrastructure and urban farming.

**678 Environmental Impact Network Analysis of US Cold Food Supply Chain Post-Processing Storage**

*J. Burek, University of Arkansas / Chemical Engineering; D. Nutter, University of Arkansas / Department of Mechanical Engineering*

More research is necessary to understand the effects of an increasing global food cold supply chain. The role of distribution centers is to move or store food and other products. We felt compelled to assess the cold supply chain in the United States and identify which food had the highest and lowest storage impacts. The research provided national and state-level environmental impact assessment of cold storage in the United States. The multi-facility building network case study was based on the whole U.S. cold food supply freezer and cooler network. Distribution centers were characterized by zones within the building (cooler, freezer, and subfreezer), location, climate zones, typical meteorological year (TMY3), energy source for electricity production, and equipment. Furthermore, the research provided national-level environmental impact assessment of different food in cold storage. Finally, the research established procedures to calculate environmental impact of post-processing food cold storage in different states. In this research we used a life cycle assessment (LCA), and reported water, energy, and climate change impact of distribution centers based on geographic location. We used regional water consumption data and applied Available Water Remaining (AWARE) method, which provided assessment of water use based on building locations. Thus, this work also contributed to research in water-energy-food nexus. Some important findings included: 80% of energy use is attributed to dock, where food is loaded and unloaded. Previous research in food sustainability accounted only for average refrigeration of storage. Food storage added from 11% (dairy) to 78% (raw vegetables) to food global warming environmental impact. The models originating from this research are comprehensive process-based LCA models, which include accurate and reproducible building energy data. The models can be adapted for any other cold supply chain in the world, they allow performing scenario analysis including the indirect factors, such as change in technology and supply chain effects and external factors such as refrigerator choice and energy efficiency. The results will serve as benchmark to improve sustainability of distribution centers, and consequently food distribution.

**679 Valuing Organic Waste-to-Energy Systems**

*C.D. Scown, Lawrence Berkeley National Laboratory / Energy Analysis & Environmental Impacts; H. Breunig, Lawrence Berkeley National Laboratory; O. Kavvada, Lawrence Berkeley National Laboratory / Energy Analysis & Environmental Impacts*

Heterogeneous organic waste resources, particularly high-moisture wastes, are some of the most challenging feedstocks to derive value from because of the limited options for processing and the short time window during which such wastes can be stored. Municipal organic waste, for example, must be processed within 48 hours in California, once delivered to a facility. From an avoided impacts perspective, however, these wastes are also the most important to divert from landfills: they are fastest to degrade in landfills, meaning as much as half of fugitive methane emissions escape before the cells can be capped and gas capture system begins operating. Understanding the net greenhouse gas (GHG) and air pollutant emissions associated with the base case management of wet organic wastes, and the competing options for waste-to-energy systems is complex. Co-products, such as compost and biochar, introduce significant uncertainty as their role in soil carbon sequestration and avoided fertilizer application are highly variable by location and soil type. We present a detailed life-cycle assessment, with a primary focus on net GHG and air pollutant emission inventories, comparing both conventional and advanced strategies for utilizing wet organic wastes. Our study provides both a generalizable framework for analysis, accounting for co-products and ambiguity as to what the single functional unit should be, as well as two sets of case study results for actual facilities in California making use of food waste, manure, and green waste. We will present the GHG and air pollutant tradeoffs associated with different strategies, and highlight methodological choices that, while sound, may result in surprising or counterintuitive incentives. We will also highlight important data gaps requiring further research, and their resulting impact on uncertainty in the final results.

**680 Quantifying the potential environmental impact benefits of bio-derived polymers in bio-based composites for construction**

*S. Miller, University of Califorina Davis / Civil and Environmental Engineering*

The rising demand for construction materials is leading to significant consumption of natural resources and environmental impacts. The depletion of resources and the environmental concerns associated with currently available construction materials are pushing exploration of alternative materials. Among these alternative materials is the use of bio-derived material resources in the production of bio-based composites. Exploration of these composites has commonly included replacement of synthetic fibers with natural fibers and more recently, the replacement of fossil-derived polymers with bio-derived polymers, thus creating fully bio-based composites. Most research on these materials has focused on mechanical and material property assessment overlooking the relative benefits or drawbacks in environmental impacts from the use of bio-derived polymers as opposed to fossil-derived polymers. This presentation will examine greenhouse gas emissions and embodied energy, two critical areas of assessment in the comparison of bio-derived resources relative to fossil-derived resources, for several bio-based composites. Findings based on cradle-to-gate production of several wood fiber reinforced composites will be presented: three with fossil-derived polymer matrices and three with bio-derived polymer matrices. Results from this work suggest notable reductions in greenhouse gas emissions for use of bio-derived polymers; however, findings are not as pronounced in embodied energy for these composites. By combining environmental impact assessments with material properties from the literature, this work shows that through tailoring of fully bio-based composites environmentally desirable alternatives to conventional materials could be developed.

**681 Production and Use of Environmental Product Declarations for Pavements**

*J. Harvey, University of California, Davis / Civil and Env Engr; J. Meijer, The Right Environment; A. Butt, University of California, Davis / University of California Pavement Research Center; A. Mukherjee, Michigan Technological University / Civil & Environmental Engineering*

Similar to nutrition labels for processed foods, environmental product declarations (EPD) are published by product manufacturers to communicate the potential environmental impacts of a product or process. The International Standards Organization (ISO) has established processes that use life-cycle assessment (LCA) methods to declare the environmental impacts on product labels, called Type III EPDs. The pavement materials industries, the Federal Highway Administration, consultants and academics have been working together developing detailed guidance for producing EPDs for pavement materials, clarifying how they can be used, and technology transfer. The objectives of producing (materials producers), and requiring and using (agencies and other owners) EPDs are to: Make LCA-based information and additional information on the environmental aspects of products widely available and understandable. Assist purchasers and users to make informed comparisons between products. Encourage improvement of environmental performance in a fair and transparent manner. EPDs are produced following Product Category Rules (PCR), and in the U.S. most pavement material PCR operators are accredited certification bodies or industry organizations for a given product. In Europe, every country has a single national program operator for all products that is a non-profit organization. Harmonization of PCRs within the supply chain and between competing industries is an issue in the U.S. A comprehensive strategy is needed to review and reconcile

PCRs around standardized procedures. These issues have led to the discussion of whether there needs to be single PCR for the U.S., and creation of a governing consortium to manage the PCR. EPDs are being routinely produced and requested by agencies in several northern European countries. Although there are a number of benefits, there are also risks for industry in their production of EPDs and for agencies requesting them due to the lack of consistency across the PCRs under which EPDs are issued. Industries need agencies to strengthen the market by responding to the industry investment in the development of PCRs and EPDs, which means that agencies need to start requiring EPDs (several states have started). A general strategy and an approximate timeline for agencies based on the results of an FHWA supported workshop have been developed.

**682 Sustainability of building-scale net-zero water systems through an LCA lens**

*V. Hasik, University of Pittsburgh; H. Gardner, M. Bilec, University of Pittsburgh / Civil and Environmental Engineering*

Various green building rating systems advocate for buildings' implementation of rainwater harvesting and wastewater reuse to mitigate water scarcity and water quality issues; however, regional and technological factors may make implementation of some building-scale water systems less desirable on a life cycle basis, especially when considering direct on-site emissions and additional material and energy inputs. We used life cycle assessment to quantify the impacts of two state-of-the-art green buildings with net-zero water systems, considering their use of materials, energy, and direct on-site emissions. The two systems are similar in size but feature slight differences in their setup, with one being almost fully closed-system, while the other utilizing more traditional open-system setup. Other differences include different active treatment technologies, storage tank sizes and materials, and piping networks. Preliminary results of the material inputs reveal the effect of material selection for piping and storage tanks, enabling a 10% reduction in the global warming potential and a 45% reduction in fossil fuel depletion categories from material use. The global warming potential resulting from direct on-site emissions can be reduced by up to 90% by the use of aeration in septic tanks, but even then, they can account for up to 50% of the total global warming potential of the system. Energy used by the systems can also be significant when the systems' water circulation is not optimized, even though both systems use energy from solar panels. This study reveals the tradeoffs and benefits of buildings' utilization of on-site water management technologies and highlights best strategies for minimizing their environmental impact in similar green building projects.

**683 Using Multi-physics Computational Models and Life Cycle Assessment to Inform Financing Mechanisms for Green Infrastructure**

*M.D. Lepech, J. Wu, Stanford University / Civil and Environmental Engineering Department*

A recent study indicated that between US$57 trillion to US$67 trillion in infrastructure spending is needed globally — approximately 5% of gross world product annually from now until 2030. This amount, which reflects a 60% increase over historical spending levels, is needed to build technologically-advanced, more sustainable infrastructure in developing countries, and upgrade to technologically-advanced, more sustainable infrastructure in developed countries. For many municipalities and governments, however, the systems and technologies that enable this new generation of infrastructure are out of reach because governments lack funding or justification to plan systems that are more expensive to design, more expensive to build, and (in some cases) more expensive to operate. This research links the sensing of major infrastructure systems (i.e., tunnels, bridges), the multi-physics modeling of these systems, and the optimization of their management under future uncertainty to new "science-based" credit-risk models used by global financial institutions. For publicly and privately financed sustainable infrastructure, these models enhance financial risk management methods by assessing infrastructure cost volatility more accurately over the infrastructure lifecycle for a portfolio of systems. This cost volatility of infrastructure can then be juxtaposed against revenue and overall fiscal volatility within the financial sector. These models of volatility are built from the "bottom up" using a probabilistic model of future infrastructure cash flows that are directly informed by sensing of infrastructure performance, multi-physics modeling, and optimization algorithms. This research fundamentally links the design, construction, and life cycle management of major infrastructure with the global financial system and groups of investors that finance its development and operation. To demonstrate the framework, a simple reinforced concrete infastruture element is modeled in this presentatino using a newly developed multi-physics software suite and commercially available LCA software to inform a new financial assessment.

## Assessing Contaminant Effects in Ecosystems with Multiple Stressors with a Focus on the California Bay-Delta

**685 The science underlying management of chemical contaminants and nutrients in the Sacramento-San Joaquin Delta**

*T. Collier, E.A. Canuel, V.H. Resh, Delta Independent Science Board*

As part of its charge to review science activities that support adaptive management in the Sacramento-San Joaquin Delta, the Delta Independent Science Board (DISB) is reviewing the scientific basis for assessing and managing water quality in the Delta. The first phase of this effort has focused on chemical contaminants and nutrients, which pose multiple stresses on the Delta ecosystem, and on human uses of the Delta. Classes of chemical contaminants covered included pesticides, mercury and selenium, and contaminants of emerging concern. To assess the state of water quality science in the Delta, information was gathered from: a literature review of recent publications on the topic of water quality; responses to a questionnaire distributed to several agencies; in-person interviews with individuals involved in different aspects of water quality; and public comments. We also invited presentations to the DISB, and members of the DISB attended meetings of several working groups involved with water quality in the Delta. Our main findings are: It is not clear whether water quality data being collected are sufficient to support optimal management decisions and policies, and how water quality data are being used in management decisions. This seems particularly true for ecosystem management decisions. Adaptive management, as outlined by the Delta Plan and the DISB in previous documents, is rarely built into water quality programs. Water quality too rarely enters into discussions about water supply and reliability. Water conveyance and storage can influence Delta water quality by affecting where, when, how, and how much freshwater is diverted. Although several entities in the Delta fund research and monitoring activities aimed at protecting water quality in the Delta, these resources tend to support specific compliance needs. We also made ten general findings, and provide recommendations for each finding--this presentation will summarize our findings and recommendations. We will also discuss how chemical contaminants and nutrients can combine with other stressors in the Delta to contribute to organismal- and population-level effects.

**686 Multiple stressor impacts from the San Francisco Estuary on the reproductive health of the threatened Delta smelt, *Hypomesus transpacificus***

*S. Acuna, Metropolitan Water District of Southern California; B.G. Hammock, J. Hobbs, UC Davis; S. Slater, R. Baxter, California Department of Fish and Wildlife; S. Teh, University of California, Davis / UC Davis School of Veterinary Medicine*

The physical habitat, health, and nutritional indices of Delta Smelt, *Hypomesus transpacificus,* were studied in relation to reproductive status among regions of the Suisun/Delta. Adult Delta smelt were collected from routine surveys during the spawning period by the California Department of Fish and Wildlife from 2012 to 2015. Health indices of fish were evaluated by using morphometric and liver indices. Nutritional indices consisted of RNA/DNA and liver glycogen. Reproductive indices of GSI, oocyte stage, clutch size, oocyte size, egg weight, and estrogen level were collected for most of the year classes. Spatial and temporal factors were evaluated as well as migratory status on the reproductive indices. Indices of HSI and liver lesion severity correlated with reproductive indices suggesting that hepatotoxins may have impacted the reproductive status. Nutritional index of Glycogen was found to positively correlate with reproductive indices suggesting that good nutritional status was important for improved reproductive status. Reproductive status of Delta smelt in the brackish open water bays of their distribution was poorer than Delta smelt found in the shallows of brackish marshes and freshwater wetlands, suggesting that these areas are important for spawning.

**687 Combined exposure to EDCs and elevated temperature influences development, reproduction and gene expression across generations in an estuarine fish**

*B. DeCourten, University of North Carolina, Wilmington / Biology and Marine Biology; R.E. Connon, University of California, Davis / Anatomy, Physiology & Cell Biology / School of Veterinary Medicine; S.M. Brander, Oregon State University / Environmental and Molecular Toxicology*

Understanding anthropogenic impacts, such as climate change and pollution, on aquatic ecosystems is critical for preserving biodiversity and maintaining water quality. The pyrethroid pesticide bifenthrin is a known endocrine disrupting compound (EDC) that enters watersheds through urban and agricultural runoff. Ethinylestradiol (EE2) is a common pharmaceutical that enters watersheds via wastewater effluent. Little is known about how elevated temperatures associated with climate change may affect the estrogenic activity of bifenthrin and EE2, particularly in species that exhibit temperature-dependent sex determination (TSD), such as *Menidia beryllina,* which is commonly found in the California Bay-Delta estuary. This study investigated the effects of temperature and bifenthrin exposure on development, reproductive output and gene expression in *M. beryllina* across multiple generations. Fish in the parental generation were exposed to environmentally relevant concentrations of bifenthrin and EE2, as well controls at 22°C and 28°C for 14 days prior to spawning. Embryos in the F1 generation were exposed to EDCs as larvae (until 21 dph) and then reared to adulthood (8 months) in clean water at experimental temperatures. Sex ratios of the F1 generation were influenced by both elevated temperature and EDCs, resulting in alteration of adaptive TSD. In all F2 treatments, elevated temperature resulted in fewer viable offspring, with effects of individual EDCs affecting offspring production at lower temperatures. Fish exposed to bifenthrin during development exhibited developmental deformities. Changes in gene expression were observed in two generations larval fish following EDC exposure at 28°C, including those exposed indirectly as germ cells during early life-stage exposure of parents, suggesting that these effects may be transferrable across generations. These results illustrate the importance for testing the effects of multiple stressors concurrently, as effects can last through multiple generations. Findings from this study will be useful in determining how EDCs will impact organisms and community structure in the face of global climate change.

**688 The Effects of Temperature and Bifenthrin on the Behavior and Neuroendocrinology of Chinook Salmon (Oncorhynchus tshawytscha)**

*M. Giroux, S. Vliet, University of California, Riverside / Environmental Toxicology Graduate Program; D.C. Volz, D. Schlenk, University of California, Riverside / Department of Environmental Sciences*

Coastal California has been experiencing the effects of chemical and non-chemical anthropological stressors through increasing surface water temperatures and rainstorm runoff events of pyrethroid pesticides washing into waterways, such as the San Francisco Bay-Delta. Salmonid populations in the Bay-Delta have been dramatically declining in recent decades, and the Bay-Delta is a delicate ecosystem rearing ground for juvenile anadromous salmonids. Therefore, the aim of this study is to investigate the effects of the pyrethroid pesticide, bifenthrin, and increasing water temperatures on the neuroendocrine response of Chinook (*Oncorhynchus tshawytscha*) salmon parr. Parr were reared at $11^0$C, $16.4^0$C, or $19^0$C for 14 days and, in the final 96 hours of rearing, parr were exposed to 0, 0.15, or 1.5 µg/L bifenthrin. A predatory avoidance Y-Maze behavioral assay was conducted immediately following exposures using taurocholic acid as a predatory odorant. Parr were presented a choice of clean or odorant zones, and locomotive behavior was video recorded. Plasma was harvested for thyroid hormone (T3 and T4), estradiol, and testosterone analysis using ELISAs. Brain and olfactory bulbs were collected for qPCR to analyze the relative expression of hormone and dopamine receptor genes. While no significant changes were observed in brain transcripts or hormone concentrations at any bifenthrin concentration or rearing temperature, there was a significant decrease in survival in parr reared at $19^0$C alone. Moreover, parr reared at $11^0$C and exposed to 1.5 µg/L bifenthrin spent significantly less time avoiding the predatory odorant compared to vehicle controls reared at $11^0$C . These results suggest that temperature may be impacting behavior at this juvenile stage, which may have population-level impacts on Bay-Delta salmonid populations.

**689 Multi-stressor effects of ultraviolet light, temperature, and salinity on oil toxicity in estuarine species**

*M.E. DeLorenzo, NOAA / National Centers for Coastal Ocean Science; P.B. Key, National Ocean Service / National Centers for Coastal Ocean Science; K.W. Chung, JHT, Inc. / National Centers for Coastal Ocean Science; P.L. Pennington, NOAA National Ocean Service / NCCOS SDID; E. Pisarski, JHT, Inc.; E. Wirth, M.H. Fulton, NOAA / National Ocean Service / National Centers for Coastal Ocean Science*

The cumulative and interactive stressors of chemical contaminants and environmental factors are especially relevant in estuaries where tidal fluctuations cause wide variability in salinity and temperature. Changes in depth also affect ultraviolet (UV) light penetration, which is an important modifying factor for polycyclic aromatic hydrocarbon (PAH) toxicity. The introduction of oil into estuarine systems may have different levels of effect depending on the tidal stage and time of year. Characterizing the interactions of multiple stressors on oil toxicity will improve prediction of environmental impacts under various spill scenarios. This study examined how toxicity of unweathered Louisiana Sweet Crude (LSC) oil was altered by temperature, salinity, and UV light. Several estuarine species representing different trophic levels and habitats were evaluated, including the sheepshead minnow, *Cyprinodon variegatus*, the grass shrimp, *Palaemonetes pugio*, and the mud snail, *Ilyanassa obsoleta*. These species are capable of surviving a wide range of environmental conditions, however, they were more sensitive to oil exposure when combined with abiotic stressors. UV light increased the toxicity of LSC oil in all species tested. LSC oil toxicity was also greater under elevated temperature conditions. Effects of salinity on LSC oil toxicity varied among species tested. Complex interactions occurred when more than one abiotic stressor (e.g. UV light and increased temperature) were combined with LSC oil.

**690 Contrasting multi-stressor effects on biological communities between urban and agricultural streams**

*I. Waite, USGS / Oregon Water Science Center; M. Munn, M. Meador, USGS; P.C. Van Metre, USGS / Texas Water Science Center; P.W. Moran, USGS / Washington Water Science Center; L.H. Nowell, USGS / California Water Science Center*

Multiple physical and chemical stressors can simultaneously affect the biological condition of streams. Understanding these stressor-response relations can be challenging due, in part, to natural variation, spatial and temporal variation in stressors, and interactions among multiple stressors. To address this complexity, the U.S. Geological Survey sampled 98 streams in the Midwest Corn Belt and 75 streams in the Southeast Piedmont of the United States, representing agricultural and urban disturbance gradients, respectively. Water and sediment chemistry, streamflow, and temperature were characterized for up to 14 weeks prior to ecological surveys of habitat and algal, invertebrate, and fish communities in each stream. Boosted regression tree (BRT) models were developed for biological metrics based on landscape variables (GIS models) and based on in-stream stressors (stressor models). Generally, physical habitat characteristics were more important in the agricultural gradient models; 56% of the variables selected in stressor models in the Midwest Corn Belt were habitat-based, and 12% were contaminants-based, primarily pesticides. In contrast, contaminants and flow alteration dominated the urban gradient models; 43% of the stressor variables in the Southeast Piedmont models were contaminants, and 23% were habitat. Additional stressor variables contributing significantly to both agricultural and urban models were nutrients, dissolved oxygen, and temperature. GIS models, primarily based on land-use variables, performed well in both regions. The stressor models improve our understanding of which specific stressors and stressor combinations have the strongest influence on biological condition whereas the GIS models can be used for prediction to unsampled streams.

**691 Mixtures of Fungicides and Insecticides Occur Frequently in Central California Coastal Streams with Urban and Agricultural Land Uses**

*M.W. Sandstrom, USGS / National Water Quality Laboratory; L.H. Nowell, USGS / California Water Science Center; P.C. Van Metre, USGS / Texas Water Science Center; B.J. Mahler, USGS / Water Mission Area; P.W. Moran, USGS / Washington Water Science Center*

Pesticide mixtures are prevalent in U.S. streams. To evaluate their significance as stressors on aquatic biota, it is important to measure a variety of current-use pesticides at concentrations low enough to assess potential aquatic toxicity. In 2017, the U.S. Geological Survey conducted a multistressor study that measured pesticides in 85 small streams in the central California coast region over a 6-week period. Concentrations of 253 current-use pesticides and pesticide degradates were determined by liquid chromatography tandem mass spectrometry (LC-MS/MS) in filtered stream-water samples collected weekly. There were 107 pesticide compounds detected at least once at concentrations from 1 to 10,000 ng/L, and 27 pesticide compounds were detected in at least 10% of samples. Eleven pesticide compounds were detected in more than 40% of water samples: the insecticides chlorantraniliprole, methoxyfenozide, dinotefuran, imidacloprid, clothianidin and thiamethoxam; the fungicides boscalid, carbendazim, azoxystrobin, and myclobutanil; and the herbicide prometon. Pesticide mixtures tended to be most complex at sites in mixed land-use watersheds, where as many as 17 fungicides and 22 insecticides were detected per sample. Potential for adverse effects on aquatic life were assessed using USEPA Office of Pesticide Programs (OPP) aquatic-life benchmarks and the Pesticide Toxicity Index (PTI), although no benchmarks were available for about one-third of the detected pesticide compounds. OPP acute-invertebrate benchmarks were exceeded in one or more samples at five sites by the insecticides imidacloprid, methomyl, diflubenzuron or (cumulatively) the organophosphates. OPP chronic-invertebrate benchmarks were exceeded at 20 sites by 21-day average concentrations of one or more insecticides, including fipronil, imidacloprid, and clothianidin. The fungicide pyraclostrobin exceeded acute benchmarks for fish and nonvascular plants at one site. At seven sites, the PTI predicted that pesticide mixtures would be acutely toxic to invertebrates. The study results show the utility of using a broad-spectrum, sensitive method that targets a large number of current-use pesticides to characterize pesticide mixtures and to estimate potential aquatic toxicity. Insecticides were predicted to be important stressors to aquatic organisms in the California streams sampled.

**692 Managing risk for the California Bay-Delta, the multiple sources-stressors-habitats-endpoints paradigm and implementation of adaptive management**

*W.G. Landis, Western Washington University / Institute of Environmental Toxicology*

In reality, the status of an environment is due to the presences of multiple sources of multiple stressors affecting a series of spatially located habitats affecting a number of endpoints, many of which contribute to a series of ecosystem services. This framework can be abbreviated as multiple sources, stressors, habitats and endpoints (MSSHE). However, the mental models of many scientists, regulators, policy makers and stakeholders are limited to narrow questions, limiting the answers and ignoring context. No doubt some of this limitation is due to the legislative process giving rise to NEPA, Clean Water and Clean Air Acts, FIFRA, TSCA, RCRA and CERCLA and the various State and international equivalents. This way of conducting business is like mandating that only a compass and not a GPS unit be used for navigation. Similarly, the goal of returning a system to an historical unimpacted by human state is equally fantastic. Humans alter their habitats and the structure of the resident community, whether indigenous or recent migrant. Since the late 1990s and early 2000s it was demonstrated that it was possible to estimate risk to multiple endpoints due to multiple stressors using the relative risk model (RRM) and other approaches. Beginning in the mid-2000s Bayesian networks have been used to estimate risk to multiple endpoints due to multiple stressors and now the RRM has been reformulated as a Bayesian network. It has been demonstrated by multiple groups that probabilistic ecological risk assessments that are regional in scale can be performed. Molecular interactions, such as those described by adverse outcome pathways can be integrated with environmental factors and management alternatives. Recently it was demonstrated that the Bayesian network-RRM can be a critical part of an adaptive management program. Instead of primarily technical issues the glacial pace of adoption of the MSSHE approach appears to be 1) cages of regulatory bars based on the risk assessment tools of the 1990s, 2) educational systems that produces graduates that lack fundamental understandings of causality, analytical tools and ecological interactions, and 3) jersey barriers blocking communication between stakeholders, policy makers and scientists on what is now possible.

## Current-Use Pesticides: Exposure and Effects on Non-Target Organisms and Ecosystems – Part 2

**693 Neonicotinoid concentrations in surface waters of North America – Evaluation of potential chronic concentrations**

*D.G. Dyer, Bayer CropScience / Environmental Safety; Y. Yang, T. Xu, Bayer CropScience/Environmental Fate; D. Netzband, Bayer Crop Science / Residue Chemistry; J. Tang, Bayer Crop Science / Environmental Exposure Assessment; S. Hanson, Bayer Crop Science / Environmental Affairs*

The presence of neonicotinoids in surface waters of North America has been documented in several publications, but these data tend to lack sufficient sampling frequency to evaluate the potential dissipation of residues in these waters. Neonicotinoids are known to dissipate in water through photolytic processes, but this is often not considered when evaluating concentrations from such studies. Therefore, maximum (acute) concentrations are often compared to chronic toxicity endpoints. The temporal aspects of aquatic concentrations are critical to understanding potential effects on aquatic organisms, specifically aquatic invertebrates in the case of neonicotinoids. Results from ongoing, neonicotinoid-targeted, field-scale monitoring studies in prairie wetlands will be described, along with an evaluation of the temporal and spatial aspects of the observed water concentrations.

**694 Large-scale risk assessment of pesticides in Canadian Prairie wetlands**

*E. Malaj, K. Liber, University of Saskatchewan / Toxicology Centre; P. Badiou, Ducks Unlimited Canada / Institute for Wetland and Waterfowl Research; C. Sheedy, AAFC / Trace Residue Analysis and Immunochemistry; J. Headley, K. Peru, Environment and Climate Change Canada / Watershed Hydrology and Ecology Research Division; C.A. Morrissey, University of Saskatchewan / Biology*

Wetlands are essential freshwater ecosystems in the Canadian Prairie Pothole Region (PPR), but they are frequently contaminated with pesticides, as a result of intensive agricultural activities in the region. We conducted a large-scale monitoring program examining the distribution and occurrence of a large suite of 169 current-use pesticides (insecticides, herbicides and fungicides) including groups of particular interest, such as neonicotinoid insecticides, and assessed the risk that they pose to wetland aquatic ecosystems. To prioritize sampling areas, we used a pesticide distribution model developed from land use imagery, and recent pesticide use survey data. Approximately 160 wetlands spanning the three Canadian Prairie Provinces were monitored for pesticides. These wetlands were predominantly semi-permanent ponds located in croplands. Water samples were collected pre-seeding (April/May) and post-seeding (June/July) in 2017-2018 with one additional monitoring campaign in the fall of 2017. Pesticide concentrations in water samples were compared against relevant ecological thresholds to determine the ecological risk to wetland health. In 2017, 63% of the wetlands had at least one pesticide detected. In total, 22 pesticides were detected, mainly in spring and summer. Some of the most frequently detected pesticides included neonicotinoid insecticides (i.e., thiamethoxam[18%]), the fungicide metalaxyl (15%), and the herbicide MCPA (50%). Concentrations of clothianidin and thiamethoxam exceeded ecological relevant thresholds at 45% and 40% of the sites, respectively. Mixtures of two or more pesticides were observed in 74% of sites (range 2-8 compounds per site). These mixtures occurred more frequently in the southeastern part of the PPR. The spatial distribution of pesticides varied by land use, with high concentrations detected in wetlands surrounded by canola and wheat crops. Overall, these results will help prioritize areas for further study, and establish the most relevant agrochemicals by mass and toxicity in the Canadian Prairies.

**695 Assessing Avian Exposure to Current-Use Pesticides**

*M. Gross, USGS / Chemistry; T. Bean, Smithers Viscient / Avian Toxicology; A. Elgin, University of Saskatchewan / Department of Biology; C. Eagles-Smith, USGS / Forest and Rangeland Ecosystem Science Center; B.A. Rattner, USGS / Patuxent Wildlife Research Center; C.A. Morrissey, University of Saskatchewan / Biology; M.L. Hladik, USGS / California Water Science Center; K.M. Kuivila, USGS / Oregon Water Science Center*

Many pesticides are currently applied in both agricultural and urban settings, resulting in chemical residues in various environmental compartments. Non-target organisms are exposed to a mixture of pesticides through direct and indirect pathways, potentially resulting in adverse effects. Pesticide exposure of biota is often modeled using concentrations detected in external media (water, sediment, soil, air). However, direct measurements of pesticides and metabolites in biological tissues may better characterize exposure and potential toxicological endpoints. Herein, we report on three field and laboratory studies to evaluate exposure of birds to current-use pesticides. Shorebirds breeding in the Pacific Northwest, US are exposed to pesticides from surrounding agricultural fields and water bodies. Analyses revealed that shorebird eggs contained five fungicides and two insecticides with concentrations varying by site and species, demonstrating that birds accumulate pesticides and transfer residues to their eggs. Next, a kinetic study was conducted with Japanese Quail (a model seed-eating avian species) dosed with treated wheats seeds containing one insecticide (imidacloprid) and three fungicides (metalaxyl, tebuconazole, fludioxonil). Pesticide and metabolite residues were quantified in brain, liver, kidney, muscle, plasma, and feces to determine their distribution and fate. Imidacloprid, tebuconazole, and metalaxyl were detected in all tissue samples and metabolites were observed for imidacloprid and tebuconazole. Imidacloprid metabolites were much more prevalent than the parent compound in all tissues except brain, highlighting the importance of screening for both pesticides and their metabolites in biological samples to holistically examine exposure. We then returned to the field to estimate pesticide exposure of Tree swallows (insectivores) from an agricultural region in central Saskatchewan, Canada. Non-lethal sampling techniques were used to collect food boluses from nestlings and blood from adults. Analyses of over 150 pesticides, metabolites, and degradates were conducted to determine environmental and dietary exposure. Analytical methods must continually evolve to monitor new inputs and transformation products in different biological matrices. This approach permits toxicologists and ecologists to link tissue concentrations of pesticides and metabolites to potentially adverse effects.

**696 Risks of insecticide exposure on monarch butterfly (Danaus plexippus) at the patch and landscape scales**

*N. Krishnan, Iowa State University / Entomology; K. Bidne, R.L. Hellmich, US Department of Agriculture; J.R. Coats, Iowa State University / Entomology; S.P. Bradbury, Iowa State University / Natural Resource Ecology and Management*

North American monarch butterfly populations have declined by over 80% in the last two decades, and its potential listing as a threatened species is currently under review. To increase the eastern monarch population, milkweed (*Asclepias* species), the host plant of monarch larvae, need to be established in the agricultural landscapes of the U.S. Midwestern states. As insecticides are often used in these landscapes, it is important to assess the risks of insecticide exposure on monarch larvae at the patch and landscape scale. Larvae could be exposed to spray drift from foliar applications through the cuticle or by consuming milkweed leaves containing insecticide residues. Previously, we reported on risks from cuticular exposure; this presentation reports risks from oral exposure. Oral toxicity studies were undertaken with beta-cyfluthrin (a pyrethroid), chlorpyrifos (an organophosphate) chlorantraniliprole (an anthranilic diamide) and imidacloprid, clothianidin and thiamethoxam (neonicotinoids). Dose-response curves generated from acute studies were compared with exposure estimated from a spray drift model (AgDRIFT). For aerial applications, predicted percent mortality for 3rd instars ranged from 99% to 89% and 93% to 16% at the edge of field and 100 feet downwind from treated fields, respectively. Predicted mortality rates were higher for chlorantraniliprole and chlorpyrifos and lower for thiamethoxam. Chronic oral toxicity studies are in progress to assess risks to larvae from dietary exposure to seed treatment insecticides absorbed by milkweed downslope of corn and soybean fields. The estimated larval survival and developmental rates derived from field scale assessments are being incorporated into a projection model to predict the number of adult monarchs recruited at the landscape level. This research will help inform the conservation costs and benefits of establishing habitat in areas potentially exposed to insecticides.

**697 Decline of aquatic insect abundance and diversity in Santa Barbara creeks potentially related to increase in use of neonicotinoids and fipronil**

*J. Murray, City of Santa Barbara / Creeks Division; J. Brinkman, Ecology Consultants; S. Cooper, University of California, Santa Barbara / Department of Ecology, Evolution, and Marine Biology; C. Garnand, Santa Barbara County / Project Clean Water; M.L. Hladik, USGS / California Water Science Center; H. Lenihan, University of California, Santa Barbara / Bren School of Environmental Science and Management; E.B. Muller, Norwegian University of Science and Technology / Department of Biology; C. Clark, City of Santa Barbara / Creeks Division*

We analyzed annual data from nine streams to determine if sensitive benthic macroinvertebrate (BMI) metrics changed from 2000 to 2012 in Santa Barbara creeks during a time of rapid increase in the use of imidacloprid, other neonicotinoids, and fipronil. This study was motivated by hydrochemical monitoring of stream and estuarine sites in Santa Barbara, which revealed frequent exceedances of biological chronic toxicity thresholds for imidacloprid and fipronil for weeks after storm events. We focused on temporal changes in mayfly (Emphemoptera) abundance given the reported high sensitivity of this group to chronic, low levels of imidacloprid, as well as changes in total invertebrate abundance owing to documented general declines in winged insect abundance. After controlling for the effects of land use and annual rainfall using multiple regression analysis, we found a significant decline from 2000 to 2012 for several invertebrate metrics (standardized regression coefficient, *p* value), including log[invertebrate abundance] (-0.35, < 0.0001), log[non-Baetid mayfly abundance] (-0.24, < 0.0001), insect taxonomic richness (-0.19, 0.001), logit[proportion shredders] (-0.13, 0.05), and EPT richness (-0.12, 0.03). These declines were detected in streams across the land use spectrum (moderately to heavily affected by urban and/or agricultural development, as well as reference locations). Invertebrate metrics were not related to regional mean air temperature (previous year or previous spring). Metric values at references sites may have declined owing to pollutant impacts (e.g., broad scale pesticide dispersion, lack of adult invertebrate dispersal from impacted sites, pesticides leached from dogs along hiking trails) or to direct (temperature, but see above) and indirect (dissolved oxygen) factors related to climatic cycles and trends. These results do not provide a direct connection between systemic pesticides and invertebrate metrics or discount other long-term drivers of invertebrate change; however, to date, the only pattern we have found suggests an association between invertebrate declines and increasing neonicotinoid use, emphasizing the importance of expanded research on this topic.

**698 Impact of neonic use in intensive agriculture on aquatic invertebrate community health: Analysis of long-term invertebrate biomonitoring database**

*I.M. Rodea-Palomares, Bayer CropScience LP / Environmental Toxicology & Risk Assessment; C. Hassinger, J. Chen, Bayer CropScience LP; S.P. McGee, Bayer CropScience LP / Environmental Health Sciences*

Neonicotinoids (neonics) are considered a major innovation in agriculture with their ability to manage destructive agricultural pests at lower rates with more favorable ecological profiles than many alternatives. However, in recent years, concerns with regards to the ecological safety of neonics to aquatic invertebrates have increased. Iowa has the highest estimated use of neonics in the USA, based on total active ingredient applied, and maintains a statewide aquatic invertebrate monitoring network (more than 900 sampling locations) with extensive historical data, making it an ideal case study to retrospectively evaluate the potential impacts of neonic use on aquatic invertebrate community health function. We used aquatic invertebrate monitoring data obtained from the Iowa monitoring program to investigate whether aquatic invertebrate health and system function are associated with the intensity of neonic use in the watershed, and if increasing neonic use over time results in decreased aquatic invertebrate community health or impaired function. For each aquatic invertebrate sampling location, the contributing watershed area was calculated as well as the annual percent cropped area (PCA) for crops with potential neonic use. We found no correlation of watershed area or PCA with an index of aquatic invertebrate health or system function. Further, our analyses demonstrates the overall health of Iowa's aquatic invertebrate communities has been preserved despite the increased extent and geographic footprint of neonic use in Iowa associated with registration of new uses and adoption of the technology. These findings provide real world, large scale evidence, that current registered uses of neonicotinoid insecticides are safe to aquatic invertebrate communities.

**699 Seasonal alterations in the effects of neonicotinoid insecticide mixture toxicity on the prevalence of marine crustaceans in estuarine areas**

*T. Hano, K. Ito, N. Ohkubo, H. Sakaji, National Research Institute of Fisheries Science / Japan Fisheries Research and Education Agency; A. Watanabe, Research Institute of Cultivation Resources / Fisheries Research Center / Ehime Research Institute of Agriculture, Forestry and Fisheries; T. Sato, T. Sugaya, T. Onduka, M. Ito, K. Mochida, National Research Institute of Fisheries and Environment of Inland Sea / Japan Fisheries Research and Education Agency*

In the present study, we evaluated the impact of neonicotinoid insecticides on the estuarine decapod crustaceans kuruma prawn (*Penaeus japonicus*) and sand shrimp (*Crangon uritai*), using a mixture toxicity model. Initially, 96 h toxicity studies were performed in the laboratory using the crustaceans with a body length of 12–17 mm. Kuruma prawn was observed to have a higher sensitivity to insecticides than that of the sand shrimp. The 96 h EC50 values ranged from 14 µg/L (clothianidin; Clo) to 943 µg/L (thiamethoxam) for kuruma prawn and from 255 µg/L (Clo) to 5,181 µg/L (nitenpyram) for sand shrimp. In subsequent field studies, 145 ambient water samples were collected at four estuarine sampling sites in the Seto Inland Sea of Japan, from June to December in the years 2015–2017. Crustaceans were harvested each month at one of the sampling points. The presence of the crustaceans was noted, and the occurrence of insecticides in estuary waters was measured. Five out of the seven neonicotinoid insecticides were identified in the estuarine water samples. The main insecticides detected were dinotefuran (Din), imidacloprid (Imi), and Clo at the following concentrations (with detection frequencies): < 0.001–0.74 µg/L (99%), < 0.004–0.18 µg/L (34%), < 0.002–0.07 µg/L (31%) respectively, when the concentrations were adjusted to salinity 20. Moreover, the occurrence of the insecticide showed temporal trends, which were correlated with their use in rice cultivation. Din and Clo were detected at a higher frequency in June and September, whereas Imi was detected at a higher frequency in June. Sand shrimps were found to be more abundant in early summer (June and July), whereas kuruma prawns were more abundant in autumn (September). Data on toxicity and occurrence of insecticides in the environment was analyzed using the response additive mixture model to calculate the maximum multi-substance potentially affected fractions (msPAFs), which were 0.8% (June) and 0.3% (September) for kuruma prawn, and 0.03% (July) and 0.002% (September) for sand shrimp. Based on the temporal appearance of the crustaceans, msPAFs in estuaries were maximized at 0.3% and 0.03% for kuruma prawn and sand shrimp, respectively. The present study demonstrates that neonicotinoid insecticides can pose a seasonal risk to estuarine crustaceans, and highlights the need to consider whether ecological risk periods coincide with crustacean emergence in estuarine areas.

**700 Relative abundance trends of bird populations in high intensity croplands in the Central US**

*J.B. Belden, S.T. McMurry, Oklahoma State University / Integrative Biology; J.D. Maul, R. Brain, Syngenta Crop Protection, Inc. / Environmental Safety; L. Ghebremichael, Syngenta Crop Protection LLC*

Declining bird populations across the US have been noted in a number of studies. Although multiple explanations have been proposed as causes of these declines, agricultural intensification has often been suggested as a significant driver of bird population dynamics. We examined this relationship by comparing bird count data from the Breeding Bird Survey collected from 1995-2016 across 13 states in the central US, to corresponding categorical changes in land cover within a 2 km radius of each survey transect using spatially explicit USDA-NASS Cropland Data Layer. This approach allowed us to compare the slopes of counts for 31 species of birds between grassland- and cropland-dominated landscapes, and against increasing levels of cropland (all types combined) and pooled corn/soybean land cover types. Nearly all birds demonstrated significant responses to land cover changes. In all cases, the number of species exhibiting positive or negative responses was comparable and median differences in percent change per year ranged from -0.5 to 0.5 percent. Species that responded either positively or negatively did not appear to fall into any particular foraging guild. If changes in agricultural practices are a major cause of declines, we would expect to see it across the spatial scale studied and across the majority of species. While these results do not rule out that potential agricultural impacts, such as toxicity resultant from pesticide exposure, may have species specific or localized impacts, a variety of factors related to habitat are likely the most significant contributor overall. Given these results over a large spatial scale basis (multi-state) and across numerous bird species, there is not a broad general trend of greater decline in crop intensive areas.

# Chemical, Biological and Instrumental Methods for Detecting Harmful Algae Blooms and Their Natural Toxins

### MP001 Conceptual Site Models for Evaluating Microcystin Fate and Effects Following Upland Placement of Dredged Material from HAB-Impacted Waters

*K.G. Keil, M.W. Habberfield, US Army Corps of Engineers / Buffalo District; A.D. McQueen, US Army ERDC / Environmental Laboratory; B. Suedel, US Army Corps of Engineers / Environmental Laboratory*

Beneficial use of material dredged from navigable waterways—including placement for ecosystem restoration or brownfield redevelopment—is an increasingly favored dredged material management method. However, dredged material impacted by harmful algal blooms (HABs) potentially introduces algal toxins (e.g., microcystins) to these beneficial use environments, with subsequent new exposure considerations. A better understanding of the fate and effects of microcystin toxins contained within or sorbed to sediments subsequently dredged from a water body is needed in order to avoid adverse impacts. Recent sampling and analysis of dredged material indicates possible persistence of microcystin toxins in the upland environment one year after dredged material was removed from Lake Erie and placed upland. Conceptual site models were developed to discern the transfer, transformation, and exposure potentials for microcystins via upland or nearshore placement of dredged material. Additionally, critical data gaps that are limiting the understanding of fate and effects of microcystins in upland environments were identified. Several key research areas were identified, including persistence, degradation processes, and bioavailability of microcystin toxins in dredged material with varying characteristics (such as grain size and organic carbon content) and process methods (such as discharge and dewatering). Significant information gaps also exist for characterizing human health risks associated with exposure to microcystin toxins in the upland environment, with current research generally limited to exposure through drinking water and uptake into agricultural crops via impacted irrigation water. Although similar research is being conducted for land application of water treatment residuals that contain microcystin toxins removed from drinking water, dredged material and water treatment residuals have different chemical, physical, and biological characteristics which may affect microcystin fate and effects from these exposure scenarios.

### MP002 Prevalence of sediment-bound microcystin-LR detections in California's Stream Pollution Trends (SPoT) Program

*K. Siegler, University of California, Davis / Environmental Toxicology; E. Stanfield, California State University, Monterey Bay; B.M. Phillips, B.S. Anderson, University of California, Davis / Environmental Toxicology; J. Voorhees, Marine Pollution Studies Laboratory / Environmental Toxicology; S. Zamudio, L. McCalla, R.S. Tjeerdema, University of California Davis / Environmental Toxicology*

Microcystins are an hepatotoxic class of cyanotoxins which affect diverse taxa. Microcystins may persist in the environment for weeks to months, posing a threat to drinking water and aquatic habitats. While some variants display a high affinity to bind to sediment, most monitoring efforts have focused exclusively on water samples. California's Stream Pollution Trends (SPoT) Monitoring Program assesses long-term trends in sediment contaminants and toxicity. In collaboration with California State University Monterey Bay (CSUMB), an optimized method for extraction of MC from sediments was developed to analyze SPoT sediments. Sediment-bound microcystin was extracted and purified using a modified sodium pyrophosphate and solid-phase extraction column method and quantified with enzyme-linked immunosorbent assay (ELISA). Annual samples from fifty sites statewide were analyzed between 2014 and 2016. Microcystin-LR, one of the most common and toxic variants, was detected in 57% of samples in 2014, 33% in 2015 and 56% in 2016, at median concentrations of 0.38 ng/g, 0.176 ng/g, and 0.183 ng/g, respectively. Ten samples were extracted and analyzed separately for external method validation using both ELISA and LC-MS. Relative percent differences in the ELISA ranged from 16% to 174%. Individually, four sites showed significantly increasing concentrations (8%), but no sites showed significant decreases. To assess seasonal trends, four sites were sampled and analyzed quarterly (n=12 per site), but no significant trends in detections or concentrations were observed. There were no significant relationships between microcystin concentrations and proximate land use, measured toxicity and contaminants, or conventional field water quality measurements. Bioaccumulation of microcystin was confirmed with a 7-day laboratory exposure of the midge *Chironomus dilutus*. Microcystins can bioaccumulate in numerous taxa, with feeding being the most important route of exposure, but it is suggested that biomagnification is unlikely because of depuration and excretion. Additional studies are needed to determine the ecological relevance of microcystin concentrations in California sediments.

### MP003 Tissue Distribution of Domoic Acid in Field-collected Crabs from the California and Oregon Coasts

*B. Stanton, OEHHA / Cal EPA / Pesticide and Environmental Toxicology Branch; S. Murphy, S. Klasing, California EPA Office of Environmental Health Hazard Assessment; A. Manderson, J. Dowell, Oregon Department of Agriculture; C. Grant, California Department of Public Health*

Federal action levels for domoic acid (DA) in seafood drive federal and state efforts to protect human health. Action limits are tissue-specific, with 30 ppm for Dungeness crab viscera and 20 ppm for all other seafood, including Dungeness crab meat. California applies the Dungeness crab viscera action limit of 30 ppm to Rock crab viscera. Existing data, including published studies, show that DA preferentially accumulates in viscera of shellfish and finfish. In limited paired testing in California, DA occasionally has been found in crab meat above the 20 ppm threshold; however, this has only occurred when viscera exceeded the 30 ppm threshold. However, the specific range of DA concentrations in viscera at which the crab meat may exceed the action level has not been determined. In this study, DA in paired meat and viscera of Dungeness and Rock crabs from California and Dungeness crab from Oregon were evaluated to understand the relationship of DA in viscera and meat, and determine whether DA in viscera could be used to predict DA in meat in different species. Our Dungeness crab data show there is a statistically significant positive association between DA in meat and viscera, consistent with the earlier laboratory study for that species (Schultz et al., 2013). Rock crab data show a similar pattern, but the association is not significant. Further evaluation of this relationship could provide a clearer indication of when both meat and viscera need to be tested for DA.

### MP004 Bioaccumulation and toxicity of anatoxin-a: Global review and in vivo bioconcentration study

*L.M. Lovin, Baylor University; S. Haddad, B.W. Brooks, Baylor University / Department of Environmental Science*

Harmful algal blooms (HABs) are worldwide phenomena exacerbated by climate change and nutrient enrichment that can lead to environmental, economic, and human health risks. Anatoxin-a is a common neurotoxin produced by multiple cyanobacterial genera during certain HAB events. It acts as a potent post-synaptic nicotinic agonist, which may lead to convulsions, respiratory paralysis, and death. Anatoxin-a has been shown to bioaccumulate in multiple laboratory and field studies with fish, canines, aquatic plants, avians, and invertebrates. However, little has been done to describe the influence of pH on the bioaccumulation of this ionizable weak base (pKa 9.4). For this reason, uptake and depuration of purified anatoxin-a was evaluated in a model organism, channel catfish (Ictalurus punctatus), exposed at 1 µg/L for 96 h followed by a 96h depuration at two pH levels: 6.5 and 8.5. Fish, water, and plasma samples were taken at 1, 3, 6, 12, 24, 48, 72, and 96h during the uptake phase and at 6, 12, 24, 48, 72, and 96h during the depuration phase. Anatoxin-a was measured using LC-MS/MS. Contrary to previous studies, we observed no anatoxin-a in the fish plasma or tissue during either exposure.

However, the exposure concentration in the current study was two orders of magnitude lower than previous studies. Paired with this analysis, bioaccumulation and toxicity data on anatoxin-a were collated from published studies to identify data gaps and elucidate the potential for anatoxin-a intoxication in various organisms. Data show species specific differences in relation to uptake into various fish tissues with a max of 37.4 µg/g found in Abramis brama gills. In most aquatic plants anatoxin-a was readily taken up, then depurated. Studies with wild avian species found anatoxin-a in liver, gut contents, intestines, and fecal pellets. Anatoxin-a was observed to elicit responses as low as an 0.5 µg/L in the reproduction rate of the rotifer Asplancha girodi. Few studies have looked at chronic effects of anatoxin-a, additive or synergistic effects with other toxins or toxicants, or bioaccumulation in invertebrate organisms. The current study demonstrates that at an exposure concentration of 1 µg/L we do not reasonably expect significant bioaccumulation of anatoxin-a to occur at environmentally relevent pH ranges of 6.5-8.5, and shows multiple data gaps in bioaccumulative and toxicological studies with anatoxin-a.

### MP006 Quantifying cyanoToxin effects on Fathead Minnows using an online monitoring system

*J. Allen, J.M. Lazorchak, USEPA / Office of Research and Development*

An online monitoring system, AQUATEC, has been developed which assesses behavioral changes in fish with the purpose of detecting toxic events. AQATEC uses video analytics of exposed fish to determine changes in behavior which may indicate the occurrence of stressful conditions. Fish are exposed in a flow through chamber while video of their activity is recorded. Onboard analytics provide real-time analysis of organism and group behaviors. Several parameters are evaluated including orientation, activity, and group dynamics. Experimental work to illustrate the efficacy of such a system by exposing fathead minnows (Pimephales promelas) to copper, microcystins, and prymnesins. An overview of the system, experimental protocol, and initial results will be presented.

### MP007 Acute oral toxicity of Microcystin-LR in mallard ducks

*Y. Bong, M. Bolotaolo, University of California, Davis; M. Miller, California Department of Fish and Wildlife / Office of Spill Prevention and Response; W. Smith, University of California, Davis; S. Teh, University of California, Davis / UC Davis School of Veterinary Medicine*

Harmful algal blooms (HABs ) are becoming an increasing concern worldwide. Microcystin, particularly the microcystin-LR (MC-LR) congener is the most potent and commonly detected cyanotoxin in California. MC-LR is hepatotoxic, nephrotoxic, and carcinogenic, and can be produced by several cyanobacterial species. HABs can affect the health of humans, domestic livestock, pets, and wild animals through direct exposure or bioaccumulation. Among affected animals, aquatic birds are ideal sentinel species for bloom detection and management because they are often the first wildlife to come in contact with toxic cyanobacterial blooms other than aquatic animals. However, clinical and pathological manifestations of cyanotoxicity in birds are poorly understood, and no formal case definition exists. The aims of this study are to (1) quantify the concentration of MC-LR in selected tissue using GC-MS, and (2) localize the tissue distribution of MC-LR via immunohistochemistry in mallard ducks orally exposed to MC-LR. Purified MC-LR (Cayman Inc) was reconstituted with water into four concentrations of MC-LR (0, 1.75, 5.5, and 17.5 mg/Kg). Mallard Ducks were exposed to a single dose MC-LR via oral gavage and subjected to a 14-day observation based on OECD Test Guideline 425, an internationally accepted specification for chemicals testing. Two ducks served as non-exposed control. At 14 days post exposure, blood was collected for a complete blood count and serum chemistry, and animals were humanely euthanized for postmortem examination, histopathology, immunohistochemistry (IHC), and chemical analysis via gas chromatography (GC-MS). In this study, the decreased ambulation observed in low-dose duck but not as prominent in higher dose is similar to a non-monotonic dose-response (NMDR). However, AST in high-dose duck showed 800-fold change but not in lower dose ducks. For immunohistochemistry, Microcystin-LR was localized in several organs (liver and kidney) but was enhanced in the apical region of kidney tubules after 14 days in all ducks exposed to MC-LR, and not found in control. Previous reported oral LD50 of MC-LR in mice is 5 mg/kg. In this study, there is no mortality in duck treated with 17.5mg/kg MC-LR. This suggests that ducks might be more resistant to MC-LR intoxication, but this needs to be further verified.

## Monitoring, Remediation and Ecotoxicological Assessment of Emerging Contaminants in Soil and Water

### MP008 Efficiency of Pharmaceutical and Personal Care Product Removal from Wastewater Effluent by a Constructed Wetland

*A. Wright, M.C. Black, University of Georgia / Dept of Environmental Health Science; M. Henderson, USEPA / Office of Research and Development / National Exposure Laboratory*

Pharmaceuticals and personal care products (PPCPs) are part of a larger group of contaminants of emerging concern that may have an impact on aquatic life. Constructed wetlands, a tertiary wastewater treatment process, have shown potential to be a cost effective, low energy method for removing PPCPs. The Sewanee Wetland is a pilot constructed wetland located in Sewanee, TN, operated jointly by the Sewanee Utilities District (SUD) and the University of the South. Wastewaters at SUD are first screened and aged in two lagoons. The resulting partially-treated wastewater flows into the wetland where photolysis zones, bulrush and pickerelweed plants, sediment adsorption, and microbial activities remove PPCPs from the water. This research project is on-going and will be completed in September 2018. Project goals include measuring the overall removal of PPCPs by the Sewanee Wetlands, determining seasonal or basin-specific differences in efficiency of PPCP removal, and identifying wetland characteristics that correlate with increased removal of PPCPs. Preliminary results show the wetland has low to moderate removal of the 14 PPCPs studied (-22% to 18%). Caffeine (97.74% ± 0.56%) and diphenhydramine (78.60% ± 4.99%) were removed most efficiently. Overall, PPCP removal was greatest during warmer seasons with colder temperatures having a negative effect on PPCP removal. Transformation processes dependent on microbial degradation are predicted to be most affected by reduced temperatures. Plant senescence during winter months may also hamper removal from wastewaters and potentially release compounds to the water column. Further sampling will potentially enable more robust interpretation of seasonal effects, as well as identifying potential factors affecting removal such as plant senescence, sediment disturbance, dilution by rainfall, temperature, retention time, and solar radiation.

### MP009 The occurrence and prevalence of UV filter chemicals in surface water samples in Biscayne Bay and Biscayne National Park

*S. Landeweer, Florida International University / Chemistry and Biochemistry; N. Quinete, Florida International University / Analytical Chemistry; P.R. Gardinali, Florida International University / Chemistry & Biochemistry and SERC*

Recently, much research has been done on the toxicological effects of UV filter compounds found in sunscreen on coral. They have been shown to cause developmental defects in coral planulae and reduce the overall health of reef systems. This research has led to increased public concern and even legislative action to mitigate these adverse effects. However, comparatively little is known about the in situ fate and transport of UV filters. Therefore, this study attempts to determine the actual and theoretical dissipation of UV filters into a typical the water column from a coastal lagoon. Biscayne Bay is an ideal place to conduct this research because it has large and small coral reef systems near a major metropolitan area and many locations along the bay are popular recreation spots where large quantities of UV filters can enter the ecosystem by washing off of swimmers who have applied sunscreen. The prevalence of UV filters in the environment was determined by analyzing water samples from Biscayne Bay using an online solid phase extraction coupled to a triple quad mass spectrometer with an atmospheric pressure chemical ionization source. To determine the range of concentrations that occur in the bay, water samples were taken from locations with varying levels of anthropogenic impact, including in the popular tourist destinations within Biscayne National Park. Eleven compounds were tested for: avobenzone, benzocaine, benzophenone, benzophenone-2, benzoresorcinol, p-benzoylphenol, 4,4'-dihydroxybenzophenone, dioxybenzone, enzacamene, octocrylene, and oxybenzone. The concentrations of these compounds in a preliminary survey of the northern bay ranged from below the detection limits to 23 ppt. Studies were also conducted in a laboratory setting to determine the empirical concentrations of the UV filters by coating an object with different levels of sunscreen formulations and submerging it in a Teflon-lined tank containing artificial and natural seawater.

## Epigenetics and Environmental Exposures: Mechanisms and Effects from Invertebrates to Fishes

### MP010 Assessing the developmental toxicity of the herbicide Ziram in zebrafish (*Danio rerio*)

*F. Cao, Department of Applied Chemistry / College of Sciences / China Agricultural University, Beijing; C.L. Souders II, University of Florida / Department of Physiological Sciences; O. Adamovsky, Masaryk University / Department of Physiological Sciences; S. Peng, Department of Applied Chemistry / College of Sciences / China Agricultural University, Beijing; L. Qiu, College of Sciences / China Agricultural University, Beijing,; C.J. Martyniuk, University of Florida / Physiological Sciences*

Epidemiological studies suggest that environmental exposures to the herbicide ziram, a complex of both zinc and dimethyldithiocarbamate, are associated with an increased risk to Parkinson's disease (PD). The herbicide is also reported to be highly toxic to aquatic organisms, however the mechanisms associated with ziram toxicity and the risk to PD are not fully elucidated. In this study, zebrafish embryos at 6 hours post-fertilization (hpf) were exposed to solvent control (0.1% DMSO, v/v), 1, 10, 100, and 1000 nM ziram for 96 hours. To better define the scope of toxicity, we assessed the effects of ziram on embryonic development, deformities, and larval behavior (light-dark preference). As neurodegeneration and PD are associated with mitochondrial dysfunction and loss of dopaminergic neurons, mitochondrial bioenergetics and the expression of genes in the dopamine system, as well as genes related to oxidative stress, were measured. The results showed that ziram induced lethality in a dose-dependent manner, decreased hatching rate and heartbeat, and caused notochord deformities at 72 and 96 hpf at 100 and 1000 nM. Basal respiration rate of zebrafish at 24 hpf was significantly decreased at 1000 nM ziram, suggesting that ziram negatively impacted mitochondrial bioenergetics in zebrafish embryos. Light-dark preference assays showed that total activity, the velocity in light zone, and total distance moved were significantly increased at 10 nM ziram at 7 dpf. Moreover, ziram decreased the mean time in the dark zone at 1 and 10 nM, suggesting that ziram induced a behavioral response in zebrafish larvae. No significant transcriptional responses of genes related to the dopamine synthesis (tyrosine hydroxylase 1, *th1*),dopamine transporter *(dat)*, dopamine receptors (*drd1, drd2a, drd3,* and *drd4b*), and superoxide dismutase (*sod1* and *sod2*) were detected. Taken together, these data suggest that ziram affects the embryonic development, induce mitochondrial dysfunction, and affect the behavior of zebrafish larvae.

### MP011 Development of a zebrafish hepatocyte assay to study contaminant-induced changes in DNA methylation in fish

*E. Boulanger, McGill University / Natural Resource Sciences; M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Head, McGill University / Natural Resource Sciences*

A wide variety of environmental chemicals, including metals, organic contaminants, and pesticides, have been shown to alter levels of DNA methylation in animal cells. However, relatively few studies have address mechanistic linkages between contaminant exposure, DNA methylation, and patterns of gene expression in non-mammalian models. Here, we use a zebrafish liver (ZFL) cell line to investigate contaminant-induced changes in DNA methylation and gene transcription. Initially, ZFL cells were treated with graded concentrations of known methylating (folic acid; FA) or demethylating (5-azacytidine; AZA) agents dissolved in dimethyl sulfoxide (DMSO), and incubated for 24 or 48 hrs. Cell viability was assessed via the resazurin assay in order to determine a range of concentrations of each test chemical that were not overtly toxic to the cells. The highest concentration that was non-cytotoxic was 10 uM for FA, and 0.3 uM for AZA. Global methylation of DNA isolated from harvested cells (n=5 dishes/dose group) was determined via the LUminometric Methylation Assay (LUMA). Significant hypo-methylation of DNA was detected in ZFL cells exposed to the demethylating agent, AZA ($p< 0.0001$). After 48 hrs of exposure, levels of global DNA methylation were 85.0%, 83.3%, and 77.6% for solvent control, 0.1 uM, and 0.3 uM AZA, respectively. DNA isolated from samples treated with the methylating agent, FA, appeared to be partially degraded based on LUMA results and could not be accurately analyzed. The source of this degradation is currently under investigation. ZFL cells were also exposed to the polycyclic aromatic hydrocarbon (PAH), benzo[a]pyrene, with no effect on global DNA methylation after a 24 hr exposure. In addition to measures of global DNA methylation, a qPCR assays was developed for a suite of genes associated with maintenance of DNA methylation in zebrafish, namely *dnmt1, dnmt3a1, dnmt3a2, dnmt3b1, dnmt3b2, dnmt3b3, dnmt3b4, gnmt1, mat1a, tet1, tet2,* and *tet3*. Once fully validated, this ZFL cell assay will be useful for screening chemicals in terms of their potential to disrupt DNA methylation in a model aquatic organism.

### MP012 Epigenetic and genetic mutations in Caenorhabditis elegans after multigenerational exposure to pristine and sulfidized silver nanoparticles

*O.V. Tsyusko, University of Kentucky / Plant and Soil Sciences; A. Wamucho, J. Unrine, University of Kentucky*

Adverse effects on reproduction were observed in our previous study after multigenerational exposure of a model organism a nematode *Caenorhabditis elegans* to silver ions ($AgNO_3$), pristine and aged (sulfidized) silver nanoparticles (pA-NPs and sAg-NPs). The toxicity also persisted in the rescued populations after exposure to pAg-NPs and Ag ions. The underlying mechanism of such effects has not been properly investigated. In this study, we investigated whether epigenetic modifications as well as accumulation of genomic mutations can be responsible for the observed increase in the multigenerational reproductive sensitivity. Changes in the histone methylation levels (H3K4me2 and H3K9me3), which were shown to correlate with reproduction, were selected as epigenetic markers for this study. For histone methylation experiments, the exposures were carried out using sub-lethal concentrations ($EC_{30}$ for reproduction) of $AgNO_3$, Ag-NPs and sAg-NPs in simulated soil pore water for 3 generations after which the nematodes were rescued from the exposure for another 3 generations. The levels of H3K4me2 and H3K4me3 were determined using ELISA approach. Significant increases in H3K4me2 levels were observed in response to pristine pAg-NPs. Interestingly, there seems to be no significant response to $AgNO_3$. However, the changes in methylation patterns for H3K4me2 (decrease after exposure and increase after rescue) was different from controls in sAg-NPs. For mutation evaluation, the exposures were carried out for 10 generations with the parent generation ($F_0$) unexposed for all groups. Whole genome sequencing analysis revealed significant increases in the total number of mutations (SNPs, deletions or insertions) in all Ag treatments. Shared only among treatments mutations are indicative of the possible targeted effects of the exposure. This suggests that induced germline mutations may play a role in the increased sensitivity observed previously after multigenerational exposures as this may reduce the fitness of the nematodes. Overall our study demonstrates that different mechanisms of toxicity might be involved in the multigenerational reproduction effects in response to all Ag treatments. Both increases in H3K4me2 levels and mutations seem to be responsible for response to pristine Ag-NPs while only genetic mutations are associated with response to Ag ions. For sAg-NPs, there are changes in the histone (H3K4) di-methylation as well as increases in germline mutations.

**MP013 Genome-wide Assessment of CpG-methylation Changes in Male Fathead Minnows after Exposure to 17α-ethynylestradiol (EE2)**

*W. Huang, USEPA / NERL / EMMD / IEIB; D.C. Bencic, R.W. Flick, USEPA / ORD / NERL / EMMD; A.D. Biales, USEPA / ORD / NERL/ EMMDI/ EIB*

17α-ethynylestradiol (EE2) is one of widely-used estrogenic chemicals present almost ubiquitous in aquatic environments throughout the United States and some other countries. EE2, acting as an endocrine disrupting compound, can disrupt hormonal homeostasis, leading to developmental disorders, cancer and other diseases. Exposure to EE2 is known to induce expression of vitellogenin, a precursor protein of egg yolk normally only expressed in female fish, in male fish. However, the underlying epigenomic changes associated with vitellogenin induction and phenotypic changes (e.g. feminization), are not well understood. This study was designed to gain insights into such underlying epigenetic regulation mechanisms by assessing genome-wide DNA methylation changes in CpG sites using the reduced representation bisulfite sequencing (RRBS) technology. Taking advantage of the newly improved assembled fathead minnow genome and annotation in house, we used fathead minnow as the model organism to study DNA methylation changes before and after exposure to EE2. In this study, two groups of male fathead minnow fish, each with 16, were exposed 2.5ng/L and 10ng/L EE2 for 48 hours, respectively. Two additional groups not exposed to EE2 were used control groups: one male group for negative control and the other female group for positive control. We assessed and compared DNA CpG methylation changes immediately after EE2 exposure in both male liver and brain tissues. To address question about whether these methylation changes are temporary or potentially long-term, we also identified and compared methylation CpG patterns of two groups of male fish after 7-day and 14-day depuration of EE2, respectively. This was done separately for liver and brain tissues. Overall, we found that a limited number of CpG regions were subjected to significant methylation changes immediately after EE2 exposures in male liver tissue, and number of affected CpG sites and magnitude of changes were even smaller in male brain tissue. In addition, our results suggest that CpG-sites methylation level could change quickly after exposure to EE2 while most methylation changes may be reversible after depuration of EE2.

**MP014 Impacts Sunlight Imposes on Emerging Rice Field Herbicides and Their Chemical Behaviors in the Presence of Sediment**

*E.N. Vebrosky, J. Landry, Louisiana State University / Department of Environmental Sciences; L.M. Basirico, Louisiana State Univeristy; K. Armbrust, Louisiana State University / Environmental Sciences School of the Coast and Environment*

South Louisiana is a unique region where rice fields harvest not only rice but also crayfish, and climate change has increased saltwater intrusion resulting in once freshwater systems becoming brackish water systems throughout the year. Flooded rice paddies serve as shallow water ecosystems for crayfish species, such as *Procambarus clarkii*, to thrive. This puts these macroinvertebrates at potential risk for herbicide exposure, via both the floodwater and the sediment. Newly registered, formulated, or reformulated rice herbicides including benzobicyclon (BUTTE) and quizalofop (Provisia) may be registered for use in Louisiana in the near future and understanding their behaviors is pertinent. Benzobicyclon has previously been shown to rapidly undergo hydrolysis and also photolysis and is potentially persistent in sediments. The photodegradation of each compound will be analyzed in both freshwater and saltwater with and without the presence of rice field sediment to determine laboratory simulations of the shallow rice paddy ecosystems.

**MP015 Medaka as a model for studying transgenerational effects of environmental chemicals and associated molecular changes**

*R. Bhandari, J.A. Cleary, X. Wang, University of North Carolina at Greensboro / Biology; F.S. vom Saal, University of Missouri Columbia / Biological Sciences; D.E. Tillitt, USGS / Columbia Environmental Research Center*

Health effects of past exposure to environmental chemicals on current and future generations is currently a topic of interest, as the chemicals that were once in the environment do not exist anymore, but it is believed that their effects are being carried by current generations in the form of molecular changes and may be inherited from prior generations. Hence, it is important to develop the tools that can identify the nature of past exposure and at the same time can reliably predict future consequences, particularly in terms of human and ecosystem health. Given that there is an association between epigenetic modifications and past exposure to environmental chemicals, it is possible that epigenetic biomarkers may serve as useful tools to identify the impact of past and current exposures on health issues. Our laboratory is developing a "medaka fish model" to identify common epigenetic biomarkers of the past exposure to environmental chemical contaminants. We have found that embryonic bisphenol A (BPA) and 17alpha-ethinylestradiol (EE2) exposure do not cause immediate phenotypic abnormalities in adulthood but can induce transgenerational reproductive impairment in the third and fourth generations. We also have found that these chemicals induce differential DNA methylation profile (epimutations) in germ cells and the epimutations are transferred to somatic cells in the third (F2) generation. In this talk, we will present a conceptual framework for transgenerational studies and our recent findings of transgenerational health effects and epigenetic modifications associated with reproductive impairment in medaka caused by past embryonic exposure to common endocrine disruptors.

**MP016 Oil-induced methylation of the aryl hydrocarbon receptor repressor (ahrr) promoter in Cyprinodon variegatus**

*E. Jones, R.J. Griffitt, University of Southern Mississippi / Coastal Sciences*

DNA methylation, a process by which methyl groups are added to cytosine residues on a DNA molecule, is one of the most studied epigenetic modifications. When gene promoter regions are hypermethylated, the methyl groups act to repress gene transcription; conversely, hypomethylation of promoters can result in enhanced gene transcription. Exposure to environmental xenobiotics is known to induce changes in DNA methylation patterns. One example of this is methylation of the aryl hydrocarbon receptor repressor (*ahrr*) promoter. The *ahrr* is a repressor that acts to inhibit transcription induced by the aryl hydrocarbon receptor (*ahr*) and confer protection against toxic intermediates generated by *ahr* transcription products (such as *cyp1a*). In mammals, exposure to polycyclic aromatic hydrocarbons (PAHs) can result in hypomethylation of the *ahrr* promoter and upregulation of *ahrr* mRNA transcription, providing an important adaptive mechanism to mitigate PAH toxicity. Although the impacts of PAHs on *ahrr* methylation and mRNA expression are understood in mammals, there is little information regarding these effects in fish models. To better understand this system in fish, we exposed larval sheepshead minnows (*Cyprinodon variegatus*, 4 days post-hatch) to 15 ppt sea water or high energy water accommodated fraction (HEWAF) from Deepwater Horizon source oil. Fish were exposed for 48 hours, followed by 48 hours of depuration. Using qPCR, we measured changes in expression of *ahr* related genes (*cyp1a, ahr, ahrr*) to evaluate the magnitude of response to oil exposure. DNA was also extracted and bisulfite treated, and the *ahrr* promoter sequenced to examine methylation patterns. A subset of larvae was reared to adulthood, and DNA from hepatic tissue sequenced to examine whether *ahrr* methylation patterns laid down during development were sustained into adulthood. Adults were then re-exposed to HEWAF to determine whether previous exposure to oil had any impact on the magnitude of response to PAH exposure and whether these responses correlated with *ahrr* promoter methylation patterns. These data provide an important opportunity to understand how promoter methylation regulates the aryl hydrocarbon receptor pathway and elucidate mechanisms governing adaptation to PAH contaminants in fish.

**MP017 Transgenerational epigenetic inheritance and neurobehavioral effects of chlorpyrifos-oxon from developmental exposure in zebrafish (Danio rerio)**

*C. Schmitt, J. Crago, Texas Tech University / Environmental Toxicology / The Institute of Environmental and Human Health (TIEHH)*

Chlorpyrifos is a broad-spectrum organophosphate pesticide widely used in both agricultural and residential applications. Subsequently, chlorpyrifos is a common surface water contaminant in the United States. Larval zebrafish are known to exhibit neurobehavioral alterations after developmental exposure; however, the persistence of effects of chlorpyrifos-exposed zebrafish via generational inheritance has yet to be investigated. In this study, embryos are exposed to chlorpyrifos-oxon at 10 ng/L and 10 µg/L starting at 4 h post-fertilization (hpf) to 5 d post-fertilization (dfp). Behavior assays assessing swimming behavior (distance traveled and velocity) of the exposed germline (F1) are conducted at 5 dpf and 21 dpf, with additional prey-capture assays performed at 21dpf. Data is analyzed using one-way ANOVA with Tukey HSD post hoc test. At 5dpf, samples of replicate treatments are collected in triplicate for later analysis. Remaining F1 embryos are raised to adulthood using standardized laboratory procedures. Each individual replicate and treatment of F1 embryos are spawned separately to produce the epigenetic generation (F2). F2 embryos are not directly exposed to chlorpyrifos-oxon. The subsequent study is repeated to 21dpf for F2 generation, at which time a comparative analysis of F1 and F2 are conducted. All samples collected from F1 and F2 area analyzed for gene expression at the dopaminergic pathway and regulation of global methylation. Ongoing research includes separate analysis of the embryonic activity (twitching) of exposed zebrafish, in situ hybridization, and global DNA methylation.

**MP018 Transgenerational Impact of Synthetic Estrogen on Reproduction in Oryzias melastigma**

*J. Lo, Western Washington University / Department of Environmental Sciences; M. Wan, D.R. Peterson, D.W. Au, City University of Hong Kong / Department of Chemistry*

Estrogenic Endocrine Disrupting Compounds (EEDCs) have the potential to impact an organism by mimicking natural estrogen or binding to its receptors. 17α-ethinylestradiol (EE2) is of particular interest as a synthetic estrogen because of its ubiquity and persistence in aquatic systems. EE2 is known to impair an organism's reproductive fitness and impact fertility rate, hatching success and embryo viability. Studies on the reproductive effect of EEDCs and EE2 have largely focused on the F0 and F1 generations during direct exposure. However, there is a need to investigate the transgenerational impact of these compounds on the F3 generation and beyond as modifications to the germline epigenome can cause these effects on unexposed offspring indicating a longer term impact of the initial exposure. The marine medaka (*Oryzias melastigma*) was used as a fish model to study the effect of EE2 on reproductive fitness using gonadal histology on the F4 generation. Developmental abnormalities were detected in oocytes alongside a decrease in mature spermatocytes across the high concentration exposures for the long term parental exposure group. Although this trend was established, additional work is needed to address additional transgenerational effects, particularly the underlying molecular, biochemical and physiological changes that occur to impede an organism's ability to reproduce.

**MP019 Transgenerational toxicity of biocide, CMIT/MIT in Daphnia magna: Epigenetics and proteomics analysis**

*J. Gim, N. Chatterjee, University of Seoul; J. Choi, University of Seoul / School of Environmental Engineering*

Epigenetics is the study of mitotically heritable or inheritable changes induced without alteration of DNA sequence. Such changes in diverse species, including cladocerans, have been reported to be induced by environmental stress factors and could be transgenerationally inherited without direct exposure at the descendant generation(s). Besides, proteomics is among one of the OMICS studies which can provide the snapshot of all the altered mechanisms of its phonotype. CMIT/MIT(chloromethyliso thiazolinone / methylisothiazoline) is a known biocide and widely used in water treatment processes and thus has a potential risk of an aquatic ecosystem. To this end, we have performed the transgenerational as well as multigenerational effects of CMIT/MIT in Daphnia magna in respect of epigenetic and proteomic context. To fulfil the aim of study, we employed multigenerational and/or transgenerational exposure (P0-F10) and multi-level endpoints from molecular to eco-physiological levels. We found CMIT/MIT caused changes in reproduction, behaviour, body size-spine length, heart rate, lipid contents, DNA damage, DNA methylation and in proteomics level. Taken together, our results showed that CMIT/MIT has transgenerational impacts on Daphnia magma which was observed through integrated molecular-physiological endpoints. Acknowledgement : This work was supported by the Mid-career Researcher Program (2017R1A2B3002243) through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and Future Planning.

**MP020 Functional implications of altered miRNA following a multiple stressor exposure in zebrafish (*Danio rerio*)**

*H. Ikert, B. Katzenback, P. Craig, University of Waterloo / Biology*

As the human population continues to grow, increased anthropogenic stress is placed on the aquatic environment and the need to understand the effects this will have on aquatic organisms is rising. Pharmaceuticals such as venlafaxine (VFX), a heavily prescribed and readily detectable antidepressant, are found downstream of wastewater treatment plants. As a result of climate change, increased surface water temperatures and decreased dissolved oxygen levels have been observed. In this study, a multi-stressor approach was used to determine the cumulative, sublethal effects of the aforementioned stressors on microRNA (miRNA) and proteins in adult zebrafish (*Danio rerio*). MiRNA are small, conserved, non-coding RNA which act by decreasing mRNA translation. This impacts the functional responses of downstream targets and is a method of environmental and epigenetic regulation of phenotypic responses. In order to determine functional consequences of changes in miRNA abundance, protein abundances can be quantified. Adult zebrafish were exposed to control (27°C, 100% $O_2$, 0 µg/L VFX) or stressed (32°C, 50% $O_2$, 1.0 µg/L VFX) conditions for 24 hours (acute) or 21 days (chronic). RNA was extracted from liver, gonad, and muscle tissue and RT-qPCR was performed on specific miRNA related to proteins that respond to hypoxia, heat stress, or contaminants. The same tissues were used for protein quantification using iTRAQ (isobaric tags for relative and absolute quantification). This comparison between stressed and non-stressed fish demonstrated altered miRNA and protein abundance. Interestingly, miRNA changes were different between sex, tissue, and length of exposure. This functional linkage of miRNA response to downstream, target protein abundance is crucial in understanding how epigenetic responses to environmental disruption affect fish health and fitness.

## Exposure Assessment and Modeling for Ecological Risk Assessment of Veterinary Pharmaceuticals and Pesticides

**MP021 Global scanning of selective serotonin reuptake inhibitors in the environment: Occurrence, hazards, and the impact of wastewater treatment**

*R. Mole, University of North Carolina Wilmington / Mathematics; B.W. Brooks, Baylor University / Department of Environmental Science*

As the world's population becomes more concentrated in and around urban centers, resource consumption and pharmaceutical use are also increasing, with wastewater infrastructure unable to meet growing demands. Urbanization is increasingly impacting aquatic ecosystems and potential hazards of pharmaceuticals introduced by wastewater effluents must be considered. In the present study, a global hazard assessment of selective serotonin reuptake inhibitors (SSRIs) was performed across all geographic regions and multiple matrices. A comprehensive literature search was completed and SSRI occurrence data was collected and collated resulting in 152 individual publications. Across all matrices, the majority of publications came from Europe (50%) followed by North America (38%) and Asia-Pacific (10%). There were minimal to no publications from many developing regions of the world such as Latin America, Africa, and South America. Environmental exposure distributions (EEDs) $5^{th}$ and $95^{th}$ percentiles for all SSRIs across all geographic regions were 2.31 and 3022.08 ng/L for influent, 5.25 and 841.60 ng/L for effluent, 0.81 and 127.70 ng/L for fresh water, and 0.51 and 22.31 ng/L for salt water, respectively. To estimate the potential hazards of SSRIs in the aquatic environment, individual therapeutic hazard values (THVs) of SSRIs were calculated, and the predicted percent exceedance was calculated across all geographic regions. In influent and effluent, sertraline is expected to exceed the THV 49% and 29% of the time, respectively, demonstrating the need to better understand the potential hazards of SSRIs in aquatic ecosystems. Similar assessments were also completed for effluent detections among various types of wastewater treatment technologies to investigate whether different technologies differentially impact SSRI occurrence. This unique global approach highlights the usefulness of global assessments to identify compounds requiring more toxicological attention, as well as regions where more monitoring and management are necessary.

**MP022 Identifying estrogenic and anti-androgenic endocrine disrupting compounds: Can sexual maturity status influence test outcome?**

*K. Roush, M.K. Sellin Jeffries, Texas Christian University / Department of Biology*

Exposures to some veterinary pharmaceuticals and pesticides pose a threat to the health of humans and wildlife, as some have been identified as reproductive endocrine disrupting compounds (REDCs) capable of altering sexual development, reproductive success and behavior. As such, the goal of this project was to determine whether sexual maturity status, as assessed via the prominence of secondary sexual characteristics, in male fathead minnows (*Pimephales promelas*) influences their response to REDCs. Specifically, we sought to determine whether less sexually mature males differed from more sexually mature males in their responses to 17β-estradiol (E2, a common human and veterinary pharmaceutical) and vinclozolin (VZ, a fungicide). Adult male fathead minnows were sorted by the prominence of secondary sexual characteristics, exposed to E2 or VZ for 7 days and sampled for the analysis of estrogen- and androgen-responsive gene expression. Results showed that fish with highly prominent secondary sexual characteristics responded differently to REDCs than fish with less prominent secondary sexual characteristics indicating that sexual maturity status influences REDC exposure outcome. For example, an increase in hepatic vitellogenin expression was detected in the more sexually mature males but was not detected in the less sexually mature males after exposure to E2; therefore, had less sexually mature males alone been utilized, the estrogenic effects of E2 would not have been identified. These results indicate that sexual maturity status should be taken into consideration in the implementation of screening assays as failure to utilize fish of the "appropriate" maturity status can skew test results. Ultimately, by refining existing screening assays to ensure adequate detection of pharmaceutical and pesticide REDCs, environmental assessments of these compounds will improve.

**MP023 Ocurrence and spatial-temporal trends of monensin in a mixed-uses watershed in Argentina**

*D.J. Perez, INTA / Agronomy; M. Menone, Universidad Nacional Mar del Plata / Lab de Ecotoxicologia; G. Cantón, Instituto Nacional de Tecnología Agropecuaria; E. Degeronimo, Instituto Nacional de Tecnología Agropecuaria Consejo Nacional de Investigaciones Científicas y Técnicas*

Occurrence and potential ecological risk of veterinary medicines in aquatic ecosystems of South America, is not well reported. This work attempts to generate relevant data about the occurrence, levels and spatial-temporal trends of monensin (MON) in a mixed-uses watershed of Argentina. El Pantanoso is a first-order stream located in the southeast of the Buenos Aires Province, with a catchment area of 476 $km^2$. This watershed is influenced by urban and farming activities. There is a Constructed Channel (CC) that receives the wastewater plant treatment (WWPT) discharge of Balcarce City and effluents of a feedlot production; and it is coupled to the stream in the main channel. Water samples were collected from 11 sampling sites in August and November 2017 covering the high flow and low flow periods, respectively. Sampling sites were chosen to cover from the headwaters to the end of stream in the floodplain contemplating different possible points of pollution by veterinary medicines. Samples was collected by triplicate using 1 L polypropylene bottles and stored at -20°C until analysis. Samples were analyzed using liquid chromatography coupled to a tandem mass spectrometer. The limit of detection (LOD) was set in 0.01 µg/L and the limit of quantification was estimated similarly to the LOD. MON was detected in 90% and 100% of the samples in August and November, respectively. In August, at headwaters and floodplain MON was detected at minimum levels (0.2 ± 0.03 µg/L) associated with the extensively livestock production. Highest MON levels were detected associated with cattle slaughter waste water effluent (2.6 ± 0.74 µg/L). In the CC, the levels varied from non detected at the beginning with urban and periurban influence, to 1.0 ± 0.1 µg/L downstream to the WWPT, and 0.6 ± 0.03 µg/L downstream to the feedlot production. In November, the levels no surpass 0.02 µg/L at different sites. MON occurrence become an ubiquitous emergent contaminant in this watershed. Cattle slaughter was the main point source pollution of MON and the WWPT result the secondary source of impact. The highest concentrations found close to the cattle slaughter in August could be explained for the intense rains during this period that induced a strong drainage from the treatment lagoon to the stream, because the distance between both sites is less than 0.5 km. This is the first report that describes the presence of monensin in surface waters of Argentina.

## Bayesian Network Applications for Environmental Risk Assessment and Management

**MP024 Assessing Risk at the Landscape Scale: Metapopulation Models as the Endpoint of a Bayesian Network-Relative Risk Model**

*C. Mitchell, Washington State University / School of the Environment; V. Chu, Western Washington University / Environmental Science; M.J. Harris, Whatcom Conservation District; W.G. Landis, Western Washington University / Institute of Environmental Toxicology; K. von Stackelberg, NEK Associates LTD / Department of Environmental Health; J.D. Stark, Washington State University / Dept of Entomology*

Populations are often the endpoints of interest in Ecological Risk Assessments (ERAs). However, many population-level ERAs do not integrate metapopulation dynamics, such as dispersal between subpopulations, and thus preclude an understanding of how population viability is affected by toxicants and environmental stressors at the landscape scale. In this study, Chinook salmon (*Oncorhynchus tshawytscha*) metapopulation models were integrated as the endpoint of a Bayesian Network- Relative Risk Model (BN-RRM) to assess the risk of organophosphate exposure and ecological stressors to multiple subpopulations across multiple seasons in an agriculturally impacted watershed. A stochastic matrix metapopulation model was developed using demographic data for three locally adapted spring Chinook salmon subpopulations and one hatchery subpopulation in the Yakima River Basin (YRB), WA. This model was simulated for 24 exposure scenarios, each with 200 simulations of a 50-year metapopulation projection. Subpopulation size outcomes were incorporated as the endpoint of the BN-RRM, which integrates the effects of toxicological (organophosphates) and ecological (water temperature and dissolved oxygen) pathways on Chinook salmon into a single probabilistic ERA. Risk was defined as the probability that a subpopulation would decline from the initial abundance (500,000 individuals). Results of this ERA indicated that risk for wild spring Chinook subpopulations was higher (97% for the American River and 74% for the Naches River subpopulation) than for non-wild subpopulations experiencing high dispersal with a local hatchery (30% for the hatchery and hatchery-supplemented subpopulations). A seasonal effect of stressors, driven primarily by high water temperatures in summer, was also detected where summer had the highest risk (68.7%) and winter had the lowest risk (52%). Ecological stressors made up a greater proportion of total risk in most scenarios than exposure to organophosphates. These results suggest that metapopulation spatial structure, local adaptation of subpopulations, and seasonal differences in exposure to stressors impact the distribution of risk at the landscape scale. This method of using site-specific metapopulation model simulations as a probabilistic ERA endpoint shows promise for estimating the spatiotemporal impacts of stressors on Endangered species at the metapopulation level, where metapopulation dynamics and spatial structure create complex risk dynamics.

**MP025 Bayesian network model for risk assessment based on fish embryo testing: A probabilistic weight-of-evidence approach**

*J. Moe, Norwegian Institute for Water Research (NIVA) / Section for Catchment Processes; A. Lillicrap, NIVA / Environmental Toxicology; W.G. Landis, Western Washington University / Institute of Environmental Toxicology; S.E. Belanger, The Procter & Gamble Company / Central Product Safety Dept; K.A. Connors, The Procter & Gamble Company / Environmental Stewardship and Sustainability Organization; J.M. Rawlings, The Procter & Gamble Company / Environmental Stewardship and Sustainability*

Reduction of animal testing wherever possible is requested by EU Directive 2010/63/EU. Fish Embryo Toxicity (FET) testing can be an alternative to using juvenile fish in acute toxicity testing. However, FET data are currently not accepted as a replacement to juvenile fish acute toxicity data for regulatory purposes such as REACH, without sufficient weight of evidence (WoE). The development of a WoE approach for FET data has been recommended by the European Chemicals Agency to significantly reduce the number of animals required for hazard assessments of chemicals. We propose a Bayesian network (BN) modelling approach for quantifying the lines of evidence demonstrating the relationship between FET data and juvenile fish toxicity results. BN is a probabilistic modelling methodology which is an increasingly used in ecological risk assessment as well as in environmental research and assessment more generally. The purpose of the proposed BN model is to integrate information from large ecotoxicological and physico-chemical datasets, and apply it in a WoE approach to predict fish acute toxicity of chemicals from data on fish embryo toxicity testing in combination with other predictive information. The current model has been developed from data on fish embryo and juvenile acute toxicity for more than 200 chemicals, including QSAR (n=197), LC50 for embryo (n=541) and juvenile fish (n=1459), and EC50 for algae (264) and Daphnia (n=2328). The toxicity values (EC50 and LC50 values, in mg/l) are discretized to 5 levels: very low (>100), low (5-100), medium (0.5-5), high (0.01-0.05) and very high (< 0.01). The links between nodes are quantified by conditional probability tables (CPT), where the values are obtained by two methods: counts of observations or expert judgement. The BN predicts the toxicity level of each chemical to juvenile fish by combining information in four pathways: (1) fish embryo toxicity, (2) physical and chemical properties, (3) toxicity to fish of other chemicals in the same category, and (4) toxicity to other species (algae and Daphnia). This WoE approach is being validated by comparing the BN model predictions with observed data for juvenile fish acute toxicity of each chemical. This BN model can be used to assess the risk of various contaminants to fish based on fish embryo toxicity data in combination with other available information without the need to perform fish acute toxicity testing.

**MP026 A Bayesian network approach to refining terrestrial risk assessments: Mercury and the Florida panther (*Puma concolor coryi*)**

*M.G. Barron, USEPA / Gulf Ecology Division; J.F. Carriger, Jr., USEPA / National Risk Management Research Laboratory*

Traditionally hazard quotients (HQs) have been computed for ecological risk assessment, often without quantifying the underlying uncertainties and variability in the risk estimate. We demonstrate a Bayesian network approach to quantitatively assess variability and uncertainties in HQs using a retrospective case study of mercury (Hg) risks to Florida panthers (*Puma concolor coryi*) based on Barron et al. (*2004. Ecotox 13:223*). The Florida panther is the last remaining wild puma population in the eastern U.S. Mercury exposure has been hypothesized as a contributing factor to population decline and individual panther deaths across the South Florida ecosystem. A tiered approach with Bayesian networks was developed to identify and quantify the causal risk factors, propagate uncertainties in causal relationships, and examine the refinements necessary for predicting the overlap of Hg exposure and effects distributions to calculate HQs. Multiple HQs for the Florida panther and Hg risks were calculated with the Bayesian network to examine potential scenarios based on changes to causal exposure factors. Application of Bayesian networks in the computation of HQs provides a transparent and quantitative analysis of uncertainty in risks.

## Advancing the -omics into Regulatory Frameworks: Case Studies and Perspectives

**MP027 Building Bayesian Network model for identification of causal relationships between KEs via TGF-beta signaling pathway**

*J. Jeong, S. Bae, University of Seoul / School of Environmental Engineering; C. Lim, Chung-ang University; J. Choi, University of Seoul / School of Environmental Engineering*

Defining causal pathway is a critical step for application of adverse outcome pathway (AOP) on the risk assessment. A Bayesian Network (BN) is a model that presents probabilities of the dependencies between any two variables in a graphical form. It is capable of diagnostic, predictive, and inter-causal reasoning. Transforming Growth Factor-beta (TGF- β) is a central modulator of inflammation and fibrosis. To identify causal relationships between key events (KEs) in an AOP of fibrosis via TGF-β signaling pathway, we built BN structure from expert knowledge. The BN structure consists of oxidative stress, endoplasmic reticulum stress, DNA damage, inflammation and Fibrosis. We used multi-walled carbon nanotubes (MWCNTs) as potential stressor. qRT-PCRtest were conducted on the various biomarkers related to each KE using human bronchial epithelium cell (BEAS-2B) to generate the gene expressions dataset for learning the BN model. The BN model was learned using *bnlearn* package in R statistical computing environment. The preliminary results showed that BN model has potential for identification of cause-effect relationships between the parameters. For further study, we are planning to do various dose- and time response test (using qPCR and ELISA) for missing data, so that we can integrate additional data with the BN model for increasing

accuracy and predictive power of the BN model. Acknowledgement: This work was supported by a grant from the Korean Ministry of Environment through 'Environmental Health R&D Program' (2017001370001)

**MP028 Transcriptomics for Elucidating Effects of Carbon and Boron Nitride Nanomaterials in *Pseudomonas aeruginosa***

*M. Mortimer, N. Devarajan, D. Li, P. Holden, University of California, Santa Barbara*

Development of environmental and agricultural applications of engineered nanomaterials (ENMs) requires thorough knowledge of ENM biological effects, including microbial responses. We found that the specific growth rate (aerobic, 30°C) of wild type *Pseudomonas aeruginosa* PG201, an environmentally and clinically relevant bacterial strain, was not affected by up to, and including, 10 mg/L of multiwall carbon nanotubes (MWCNTs), graphene, boron nitride flakes (BN) or carbon black (CB) amended to mineral medium. Although bacteria-ENM agglomerates were formed, no significant cell membrane damage was detected by propidium iodide/SYTO9 staining. However, transcriptional analysis by next-generation sequencing indicated differential regulation of 111, 44, 26, and 25 genes ($p < 0.05$; $\log_2$(fold change) $\geq 2$) in MWCNT, graphene, BN and CB treatments, respectively, compared to the control culture without ENMs. MWCNTs, which induced the most pronounced transcriptomic response, caused the upregulation of genes encoding general stress response, sulfur metabolism, and transport of small molecules and downregulation of genes encoding flagellar basal-body rod proteins and other virulence-related factors, nitrogen metabolism, and membrane proteins. In addition, *czcR* and *czcS*, the genes of a two-component regulatory system associated with quorum sensing, heavy metal and antibiotic resistance, were downregulated in MWCNT-exposed bacteria. Consistently, antibiotic susceptibility tests of MWCNT-treated *P. aeruginosa* showed that the minimal inhibitory concentrations (MICs) of meropenem and imipenem decreased twofold, indicating increased susceptibility of *P. aeruginosa* to two last-resort antibiotics. In summary, we show that sensitive transcriptional end points shed light on subtle physiological effects of ENMs that may be predictive of adverse outcomes.

**MP029 Building Bayesian Network model for identification of causal relationships between KEs in oxidative stress and inflammation related AOP**

*J. Jeong, S. Bae, University of Seoul / School of Environmental Engineering; C. Lim, Chung-Ang University / Department of Applied Statistics; J. Choi, University of Seoul / School of Environmental Engineering*

Defining causal pathway is a critical step for application of adverse outcome pathway (AOP) on the risk assessment. A Bayesian Network (BN) is a model that presents probabilities of the dependencies between any two variables in a graphical form. It is capable of diagnostic, predictive, and inter-causal reasoning. To identify causal relationships between key events (KEs) in an AOP of fibrosis via oxidative stress and inflammation signaling pathway, we built BN structure from expert knowledge. The BN structure consists of oxidative stress, DNA damage, inflammation and Fibrosis. Various environmental chemicals, such as, biocides and nanomaterials, were used as potential stressors. qRT-PCRtest were conducted on the various biomarkers related to each KE using human bronchial epithelium cell (BEAS-2B) to generate the gene expressions dataset for learning the BN model. The BN model was learned using *bnlearn* package in R statistical computing environment. The preliminary results showed that BN model has potential for identification of cause-effect relationships between the parameters. For increasing accuracy and predictive power of the BN model, extensive dose- and time response analysis needs to be performed. **MP030 A network approach to quantify the relationship between individual contaminants and biological responses in environmental mixture studies**

*D. Bertolatus, University of Colorado Denver / Integrative Biology; L.B. Barber, USGS / National Research Program; C.J. Martyniuk, University of Florida / Physiological Sciences; A.M. Vajda, University of Colorado Denver / Integrative Biology*

Interpreting biological effects caused by exposure to chemical mixtures is an ongoing challenge in ecotoxicology. Exposure assessments utilizing transcriptome profiling have been valuable for characterizing the effects of environmental mixtures on aquatic organisms. However, a gap remains between these assessments and the specific information needed to make regulatory and management decisions. New approaches are needed to identify the specific mixture constituents that are contributing most strongly to adverse outcomes. Here, we leverage existing chemical and transcriptomic datasets to estimate the association between the occurrence and concentration of individual chemicals and transcriptomic changes following exposure. Transcriptomic and chemical data come from experiments where male fathead minnows were exposed in situ to water from multiple locations in the Shenandoah River watershed. Exposure water was analyzed for over 550 contaminants and hepatic gene-expression profiles were measured using microarrays. Both data-driven and hypothesis-driven analyses are used to establish linkages between contaminants and biological effects in organisms. Our hypothesis-driven approach uses databases of chemical-gene interactions to develop hypotheses about the patterns of differential gene expression that are expected for an individual chemical. These hypotheses are then tested by comparing expected patterns to observed patterns in exposed organisms using Gene Set Enrichment Analysis. Significant enrichment of a gene set for a given chemical indicates that there is similarity between the expected and observed patterns of gene expression, and suggests a causal role for that chemical. The data-driven approach measures correlations between detected contaminants and individual genes. The resulting correlation matrix was used to build a bipartite network and to identify the contaminants with the highest degree (significant correlation to gene expression). Other network metrics, such as modularity and centrality, are expected to be informative for grouping chemicals with similar mechanisms of action and identifying the potential for additive mixture effects. These two approaches will help identify the subset of environmental chemicals that pose the most risk to aquatic organisms, which is necessary for conserving aquatic habitats.

**MP031 Harnessing Chemical Proteomics to Elucidate Molecular Mechanisms of Toxicity of Water Disinfection By-products**

*D. Hall, University of Toronto / Chemistry; K. Yeung, University of Toronto; H. Peng, University of Saskatchewan / Department of Chemistry*

Disinfection by-products (DBPs) from chlorine disinfected drinking water have been epidemiologically linked to a myriad of health effects including bladder cancer and premature-births. Yet, current regulations fail to account for hundreds of known and unknown DBPs — many of which are suspected to be the true drivers of toxicity. Our previous studies have shown that Nrf2-mediated oxidative stress is the primary toxic pathway of DBPs. Motivated by this, we further investigated the toxic mechanisms of two classes of prominent DBPs: halogenated acetic acids and acetamides. Cytotoxicity and oxidative stress assays revealed iodinated DBPs to be the most toxic, followed by brominated, then chlorinated DBPs. Consistent to these results, iodinated DBPs also exhibit the greatest capacity for protein binding via covalent cysteine modification. We elucidated the exact protein targets using Affinity-Based Protein Profiling chemical proteomics. We found hundreds of proteins to be covalently modified by DBPs with compound specific-patterns. Potential impacts of such modifications on protein conformation changes and functions were further evaluated using our Target Identification by Ligand Stabilization proteomics method. Molecular insights from our work provided the first evidence that covalent modification of cysteines on cellular proteins is the primary pathway by which DBPs exhibit oxidative stress-mediated toxicities. Furthermore, the fundamental research derived in the present study motivated us to develop a chemical reactivity probe for high-throughput assays to identify toxic components of DBPs from real water samples.

**MP032 Predicting adverse outcomes of selenomethionine exposure to embryonic white sturgeon (*Acipenser transmontanus*) using in-ovo microinjection**

*D. Green, University of Saskatchewan / Toxicology Centre; D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences; K. Liber, University of Saskatchewan / Toxicology Centre; N. Hogan, University of Saskatchewan / Toxicology Centre and Department of Animal and Poultry Science / College of Agriculture and Bioresources; A.J. Alcaraz, University of Saskatchewan / Toxicology Centre; T. Lane, University of Saskatchewan; K. Bluhm, University of Saskatchewan / School of Environment and Sustainability; M. Brinkmann, M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre*

Selenium (Se) is a trace element and nutrient for almost every form of life. However, it has a narrow margin between essentiality and toxicity that can be surpassed when anthropogenic activities cause elevated Se concentrations in aquatic environments. This toxicity occurs when primary producers biotransform the excess Se to selenomethionine (SeMet), a bioaccumulative methionine analogue that can be maternally transferred to the eggs of oviparous species, leading to impairment, or complete failure, of recruitment. The primary mechanism identified for SeMet toxicity is redox cycling of the metabolite methylselenol, yet not all species exposed to SeMet show signs of oxidative stress. While SeMet exposure poses potential risk to many oviparous vertebrates, the white sturgeon (*Acipenser transmontanus*) is at particular risk due to its SeMet sensitivity, life history, and endangered status. Though tissue specific (ex. egg, ovary) concentration guidelines have been employed by the United States Environmental Protection Agency, these thresholds are only capable to indicating imminent or present risk. Protection efforts could therefore be enhanced through the development of more sensitive tools capable of predicting the risks that have yet to manifest. The purpose of this study is to identify the molecular initiating event of and possible key events leading to SeMet toxicity in the white sturgeon. In order to characterize this pathway 1488 white sturgeon embryos were exposed to either negative or process control conditions, or graded SeMet injection (nominal: 8.8, 13.3 and 20 µg/g dry mass) conditions *in ovo* in four replicates to determine the potential effects of SeMet exposure in early life stage white sturgeon. Embryos were sampled five days pre and post-hatch for transcriptomic analyses, and at swim up for biochemical, histological, and apical endpoint analyses in order to delineate the causal chain of toxic events across levels of biological complexity. The results of this experiment will aid in developing a highly sensitive predictive model for SeMet toxicity and will hopefully enhance the assessment of Se risks posed to white sturgeon.

## Environmental Stewardship in a Changing Climate – An Integration of Engineering and Environmental Science

**MP033 Ecosystem services accounting in support of corporate environmental stewardship in a changing climate**

*A.M. Morrison, N.W. Gard, K.R. Palmquist, Exponent, Inc. / Ecological and Biological Sciences Practice; J. Ma, Exponent, Inc.; J. Cowles, Exponent, Inc. / Ecological and Biological Sciences*

Corporations face increasing pressure from shareholders and the public to account for environmental impacts from operations. Carbon sequestration credits (i.e., “green” or “blue” credits) are one option for offsetting greenhouse gas emissions by purchasing units of forest, mangrove, or wetland habitats, for example, but these credit projects provide additional valuable ecosystem services (e.g., biodiversity protection, flood control, contaminant sequestration, etc.) that are not incorporated into the carbon sequestration credit model. These ecological services may be of value to corporations considering purchase of such credits, and hence there is a need to understand, quantify, and track these additional ecological benefits. There is also a need for crediting agencies and credit purchasers to understand the differential risks associated with various offset projects (e.g., will climate-driven sea-level rise inundate a wetland bank before credit gain is maximized?). Finally, businesses need to weigh costs/benefits of offsetting options against consideration of other factors. For example, carbon sequestration can be performed anywhere, but there may be greater ecological benefits in some locations than others. Facility risk may be reduced, and resiliency subsequently increased, if the offsetting is done at the source of the emissions. All these factors need to be considered in a holistic assessment of the full suite of ecological benefits/risks of a carbon-offset project over the life-cycle of the designated offset. Here, we discuss how an ecosystem services valuation tool (EcoAIM) can be used to (1) quantify the ecological benefits that accrue from various credit/mitigation projects while incorporating user preferred services and (2) incorporate climate risk model scenarios to assess future climate-related changes on credit/mitigation projects and industrial operations. In this presentation, we use a hypothetical example to show how a corporation considering investing in mitigation offsetting can use a proactive risk management approach to assess future benefits and liabilities from candidate mitigation projects.

**MP034 Global climate change and its influence in planning remediation, restoration and long-term management of contaminated sites**

*W.G. Landis, Western Washington University / Institute of Environmental Toxicology; C. Menzie*

Global climate change (GCC) and the other effects of adding carbon dioxide to the atmosphere already is having and will continue to have impacts on the remediation, restoration and management of contaminated sites. The expectations are of more severe storm events, changes in precipitation amount and type, sea level rise, and ocean acidification. Given the long periods of liability for a contaminated site, often multiple decades, these changes in prevailing conditions will affect both the engineering of restoration process and the surrounding ecological structure. Therefore, GCC requires a revision of the current approaches to risk assessment and decision making. Landis et al (2013) proposed seven principles that should be followed when considering remediation actions and the supporting ecological risk assessment activities. Principle 1: Consider the importance of GCC-related factors in the ERA process and subsequent management decisions and make them appropriate to the spatial and temporal scales. Principle 2: Assessment end points should be expressed as ecosystem services. Principle 3: Responses of the ecosystem services (endpoints) can be positive or negative. Principle 4: The ERA process requires a multiple-stressor approach, and responses may be nonlinear. Principle 5: Develop conceptual cause–effect diagrams that consider relevant management decisions as well as appropriate spatial and temporal scales to allow consideration of both direct and indirect effects of climate change. Principle 6: Determine the major drivers of uncertainty, estimating and bounding stochastic uncertainty spatially and temporally, and continue the process as management activities are implemented. Principle 7: Plan for adaptive management to account for changing environmental conditions and consequent changes to ecosystem services. In the five years since the publication of these principles methods now exist to incorporate each into an appropriate risk assessment and decision making process to manage contaminated sites. Methods to address each of these principles are outlined in the presentation with examples from case studies.

**MP035 Incorporating a framework for risk assessment, risk management, and risk mitigation of extreme weather events at Superfund sites**

*J. Pietari, Exponent / Environmental Sciences; A.M. Morrison, Exponent / Ecological and Biological Sciences Practice; P.D. Boehm, Exponent, Inc. / Environmental & EcoScience Group*

More than 300 active Superfund sites are located in areas that are prone to flooding or vulnerable to sea-level rise. Increasing frequency and intensity of extreme weather events may pose severe threats to human health and the protectiveness of remedies at those Superfund sites located in high flood risk areas. Widespread flooding from Hurricane Harvey demonstrated the risks for contaminated sites: thirteen Superfund sites flooded or were otherwise damaged during the storm. At one of those sites, the San Jacinto River Waste Pits, a temporary cap covering pits with dioxin-contaminated sediments was compromised, exposing the waste material in the pits. Potential impacts from extreme weather events can include physical and operational disruptions: power outages; physical or water damage to remedial components such as caps, pumps, or onsite treatment systems; reduced access; increased erosion; or sediment deposition. Sediment erosion and/or deposition will also challenge evaluating performance or recovery as baseline or reference area conditions may change as a result of extreme weather impacts. Currently, USEPA guidance for conducting remedial investigations and feasibility studies (RI/FS), remedy design, and five-year reviews of Superfund sites does not include specific advice on how to consider extreme weather effects and, particularly, the increasing intensity and frequency of such events on the protectiveness of selected remedies. Financial impacts may include increased remedy costs resulting from characterization of impacts, repair of remedial components, or even re-design of remedies or retirement of damaged remedial components. Understanding the effects of extreme weather events necessitates a vulnerability analysis that is incorporated as early as possible in the Superfund site lifecycle. In this presentation, we will discuss potential impacts from extreme weather events on Superfund sites: impacts on operations, on the protectiveness of remedies, and on baseline characterization. Additionally, we will demonstrate a framework that can be used to evaluate extreme weather event impacts at sites at various stages of the Superfund site lifecycle, including data collection and modeling activities that responsible parties can take for sites in the RI/FS phase and mitigation and adaptation measures that existing sites can incorporate.

## Immunotoxicology: Identifying Adverse Effects, Developing New Approaches and Confronting Existing Challenges

**MP037 Effects of UV-234 and UV-320 on mitochondrial bioenergetics and immune response genes in the zebrafish (*Danio rerio*)**

*X. Liang, School of Ecology and Environment, Inner Mongolia University, Hohhot; O. Adamovsky, Masaryk University; C.L. Souders II, C.J. Martyniuk, University of Florida / Physiological Sciences*

Among the benzotriazole ultraviolet stabilizers (BUVSs), UV-234 and UV-320 are two of the most frequently detected chemicals in aqueous ecosystem. Despite some evidence for bioaccumulation in aquatic organisms, limited toxicological data on these compounds have been generated in fish. In the present study, zebrafish embryos were exposed to 0.01, 0.1 and 1µM UV-234 or UV-320 for up to 6 days. Developmental toxicity of UV-234 and UV-320 was assessed, as well as their effects on mitochondrial bioenergetics and immune response-related gene expression as there is a close association between the mitochondria and the immune system. In the UV-234 treatment, hatching time of zebrafish embryos was significantly increased compared to controls. Non-mitochondrial respiration and mitochondrial respiration of zebrafish embryos were significantly decreased at 1µM UV-234 group after 24 and 48 h exposure, respectively. There were no changes in the expression of the investigated key immune regulators, chemokines and cytokines (*tlr5a, tlr5b, mmp9, il8, tnfa, cxcl-C1c, nfkb1*, and *ifng*). In the UV-320 treatment, hatching time of zebrafish was not affected but both basal and non-mitochondrial respiration (both at 48 hours) were significantly higher in the 1 µM group compared to the control group. Moreover, the mRNA levels of chemokines (*il8* and *cxcl-C1c*)were suppressed in response to 0.1 µM UV-320 showing immunomodulatory potential of UV-320. Taken together, these data suggest that UV stabilizers may act to modulate mitochondrial bioenergetics and the immune system in developing embryos. Future studies will be aimed at discerning the interaction between mitochondria and the immune system in response to UV stabilizers

**MP038 Endocrine Disrupting Compounds and Immunity: The Effects of Estrogens and Antiestrogens on Immune Function in Fathead Minnows**

*L.R. Malin, M.G. Finch, W. Gbedey, H. Nettelblad, Texas Christian University; K. Roush, Texas Christian University / Biology; L. Thornton, University of North Texas / Biology; C. Wade, Texas Christian University; M.K. Sellin Jeffries, Texas Christian University / Department of Biology*

Estrogenic endocrine-disrupting compounds (EDCs) are ubiquitous in the aquatic environment, posing potential threats to wildlife. Research on estrogenic EDCs has focused primarily on effects on the reproductive system. However, sex steroids also affect other body systems, such as the immune system. Though few studies have sought out to determine the effects of estrogenic EDCs on immunity, known differences between male and female immune function suggest a role for sex steroids. While it is agreed that estrogens have the capacity to alter immunity in teleosts, the effects of these alterations on the organism are not currently understood. The current study both analyzed the effects on immune function of male fathead minnows (FHM) exposed to estradiol, as well as the effects on immune function of female FHM exposed to the anti-estrogen fadrozole. The effects in each group were assessed by whole-organism (i.e., pathogen resistance), tissue (i.e., spleen index), cellular, (i.e., leukocyte counts) and molecular endpoints (i.e., expression of genes associated with immune function). First, the results revealed differences between control males and control females with regard to pathogen resistance and the expression of a subset of immune-related genes, confirming previously noted differences in male and female immune function. Regarding the effects of estrogens and anti-estrogens on immunity, gene expression results suggest that the complement pathway may be under the influence of estrogens. However, estrogens and anti-estrogens do not appear to influence immune function at the tissue or whole organism level. Overall, the results of the current study point to the sexually dimorphic nature of the immune system and suggest that exposures to estrogens and/or anti-estrogens may alter some aspects of immunity. In light of these results, future studies aiming to analyze the effects of estrogen exposure on aquatic wildlife should consider potential impacts on the immune system.

**MP039 The impacts of early life stage hypothyroidism on immune function and the immune response in the fathead minnow (*Pimephales promelas*)**

*L. Thornton, University of North Texas / Biology; M.G. Finch, Texas Christian University; B.J. Venables, University of North Texas / Advanced Environmental Research Institute; M.K. Sellin Jeffries, Texas Christian University / Department of Biology*

Current evidence suggests that thyroid hormones (THs) play a role in immune function and the immune response. For example, TH receptors are expressed in immune-related tissues such as spleen and head kidney, and several types of immune cells, such as dendritic cells and lymphocytes, are capable of producing thyrotropin. There is also evidence that THs may impact the development of the immune system as organisms that experience thyroid suppression during immune development have been shown to experience alterations in the immune response and pathogen resistance during adulthood. However, the number of studies that explore the role of THs in immune development is limited, and the mechanisms leading to any alterations in overall immune function are poorly understood. It is important to elucidate the role of THs in immune development given that many environmental contaminants have been shown to disrupt

TH homeostasis and may also have negative impacts on the immune system. As such, the main goal of this study was to determine the long-term consequences of early life stage hypothyroidism on immune function. To achieve this goal, fathead minnows (FHMs, *Pimephales promelas*) were exposed to the model thyroid suppressant propylthiouracil (PTU) from Yersinia ruckeri via intraperitoneal injection and monitored for 14 days to determine pathogen resistance. At eight hours post injection, a subset of minnows was sacrificed for the determination of spleen index (spleen mass relative to total body mass), hematocrit (ratio of volume of erythrocytes to total blood volume) and bacterial load (abundance of a *Y. ruckeri* specific transcript in splenic tissue). Unexpectedly, no statistically significant alterations were detected for any of the endpoints measured, including pathogen resistance, suggesting that early life stage hypothyroidism does not impact immune function or the immune response during adulthood. Yet, it is important to note that only a single host-pathogen model was used in this study, and the consequences of a viral or parasitic infection remain unknown.

## Ecotoxicological Impact of Multiple Stressors in Aquatic Ecosystems

**MP040 Impacts of wastewater discharges on freshwater mussels in a watershed within Southern Ontario, Canada**

*E. Hayward, Trent University / Environmental and Life Sciences; P. Gillis, Environment and Climate Change Canada / Aquatic Contaminants Research Division; C.J. Bennett, Environment Climate Change Canada / Water Science and Technology Directorate; R.S. Prosser, University of Guelph / School of Environmental Sciences; C.D. Metcalfe, Trent University / Water Quality Centre*

Wastewater treatment lagoons serving communities across rural Canada were originally constructed to serve smaller populations. Growth and insufficient financial resources for upgrades have caused many communities to discharge treated wastewater that does not comply with current Federal regulations for wastewater quality. Aquatic organisms in water bodies receiving municipal wastewater are often negatively impacted by exposure to these discharges. Exposures to contaminants of emerging concern (CECs) of wastewater origin have been associated with feminization of male fish and effects on the immune system of freshwater mussels. In some areas of the Grand River watershed (ON, Canada), there are abundant populations of freshwater mussels, including several species at risk (SAR). The impact of wastewater discharged into Boston Creek, a tributary of the Grand River, was investigated in partnership with a small rural community of approximately 300 people. During the fall discharge, the wastewater in the lagoon met regulations for wastewater quality and did not cause acute toxicity to Oncorhynchus mykiss. However, in static toxicity tests with the glochidia (larvae) of Lampsilis fascilola and Villosa iris, exposure to undiluted lagoon water reduced survival. During the fall discharge from the lagoon, adult mussels (Lasmigona costata) were caged upstream and downstream of the lagoon discharge, and tissues were analyzed for various biomarkers of contaminant exposure, such as oxidative stress and induction of metallothionein. Passive samplers were also deployed in the receiving waters to characterize exposure to CECs. Results will be presented and discussed with respect to the quality of the habitat of mussels, including SARs in the watershed.

**MP041 The independent and interactive effects of TBT and hypoxia on the oyster Crassostrea virginica**

*A.F. Barnett, J. Gledhill, University of Mississippi / BioMolecular Sciences; R.J. Griffitt, University of Southern Mississippi / Coastal Sciences; K.L. Willett, University of Mississippi / BioMolecular Sciences; M. Slattery, D.J. Gochfeld, University of Mississippi*

Oyster reefs provide significant ecosystem services, including shoreline stabilization, water quality improvement, and nursery habitat for commercially important fisheries. In Mississippi, historic oyster reefs have declined dramatically – from over 400,000 sacks in 2004 to less than 30,000 sacks in 2015. While overfishing has played a major role, other stressors such as environmental contaminants, hypoxia and disease, threaten the survival of oyster reefs in the Gulf of Mexico. The biocide tributyltin (TBT), once commonly used as an antifouling paint on ships, increases mollusk susceptibility to calcification anomalies, metal accumulation, predation, disease and imposex. TBT degrades slowly in the environment, potentially persisting for decades in sediment, where it may be subject to resuspension. Although banned worldwide in 2003, enforcement against TBT use is not universal. Expansion of the port at Gulfport risks reintroduction of TBT to the Mississippi coast. Additionally, most of the Northern Gulf of Mexico is referred to as a "dead zone" due to hypoxia caused by eutrophication from the Mississippi River. This study examines the effects of TBT and hypoxia utilizing a state-of-the-art toxicology facility at the University of Southern Mississippi's Gulf Coast Research Laboratory. Oysters in replicate exposure tanks are exposed to independent and combined hypoxia and TBT treatments in a factorial design: normoxic control (> 8 mg/L dissolved $O_2$), hypoxia (< 2 mg/L dissolved $O_2$), and diluted TBTCl (80 ng/L). Exposure time-dependent physiological and molecular endpoints, including food clearance rates and upregulation of metallothionein and calmodulin, will be compared with those from a field study of oysters deployed on historical oyster reef sites in the Mississippi Sound. The results of this study not only determine how these stressors affect oysters independently and in combination, but will provide valuable insight for decision-makers involved in the restoration and recovery of oyster reefs on the Mississippi coast. This project is paid for by the SETAC Student Training Exchange Opportunity and with Federal funding through the U. S. Department of the Treasury and the Mississippi Department of Environmental Quality under the Resources and Ecosystems Sustainability, Tourist Opportunities, and Revived Economies of the Gulf Coast States Act of 2012 (RESTORE Act).

**MP042 Harnessing lipidomics to characterize multiple stressor responses in zebrafish**

*D.A. Dreier, University of Florida / Physiological Sciences; M. Nouri, University of Florida; N.D. Denslow, C.J. Martyniuk, University of Florida / Physiological Sciences*

In the natural environment, aquatic organisms encounter multiple stressors including chemical contaminants and temperature gradients. Although most environmental risk assessment frameworks offer conservative thresholds for chemical stressors, there remains a need to characterize how additional stressors affect these criteria. This is especially important for chemicals affecting metabolism (i.e., mitochondrial function, lipid metabolism), as temperature can modulate these pathways. Thus, the objective of this research was to characterize the impact of temperature stress on mitochondrial-induced toxicity during zebrafish development. In addition, we aimed to determine how chemical-temperature stressors affect lipid composition during embryonic development, as altered lipid metabolism is a common response to mitochondrial dysfunction. To accomplish these objectives, we modified the fish embryo toxicity assay (OECD Test No. 236) to increase experimental throughput for multiple stressor exposures. Zebrafish embryos (n = 16/group) were exposed to the mitochondrial toxicant 2,4-dinitrophenol at 6 concentrations (0, 6, 12, 18, 24, 30 µM in 0.03% DMSO) and 2 temperatures (28, 33°C) for 96 hours. Embryos were monitored every 24 hours for lethality and hatch. It was determined that temperature significantly increased the rate of development, thus data were analyzed as a function of degree days, which provided normalization for hatch rate. At 28°C, there was an observable decrease in hatch success at 12 µM, and no fish hatched at higher concentrations (18, 24, 30 µM). However, at 33°C, there was greater hatch success at 12 µM, and hatch was also observed at 18 µM. Similarly, there was a decrease in mortality rate at and above 12 µM for zebrafish exposed to 33°C. These data suggest that temperature may offer a protective effect during early life stages, likely due to metabolic compensation and exposure duration at specific developmental stages. In addition to these findings, we have optimized a LC-MS/MS method to characterize global lipid responses in zebrafish larvae. In optimization experiments,

our method successfully quantified 679 lipid species including cholesterol esters, sphingomyelins, triacylglycerols, and several phospholipid classes, and we will use this approach to identify novel lipid responses that underlie mitochondrial dysfunction. Taken together, these data will be useful to further define adverse outcome pathways for multiple stressors.

**MP043 Toxicity of nano-enabled azoxystrobin on zebrafish embryo**

*Y. Zhang, G. Goss, University of Alberta / Biological Sciences*

The use of nanotechnology to enhance pesticide formulations holds the promise of reduced pesticide use, reduced mobility in soils and overall improvements in agricultural practices while simultaneously maintaining yields. However, the toxicity of nano-enabled pesticides, including azoxystrobin, has not been well studied comparing to their bulk form counterparts. This study investigates both lethal and sub-lethal endpoints in zebrafish embryos up to 120 hours post fertilization (hpf) under laboratory light or simulated sunlight. The median lethal concentration (LC50) of both nano-enabled and bulk form azoxystrobin are determined. Malformations, including pericardial edema, tail deformity, yolk sac edema, and spinal curvature are observed. The gene expression of stress-related genes, including *catalase, cyp1a, gst, sod1* and *sod2*, and enzyme activities of oxidative stress-related enzymes, such as Catalase, SOD, GSH and CYP1A, are measured and compared between nano and bulk azoxystrobin. The oxygen consumption of embryos is measured at 48, 72, 96 and 120 hpf. The preliminary results show that the LC50 of nano-enabled azoxystrobin is significantly lower than bulk azoxystrobin under laboratory light. In addition, the simulated sunlight significantly decrease LC50 of both nano-enabled and bulk azoxystrobin. The results will provide important information on the toxicity of nano-enabled azoxystrobin under ecologically realistic conditions.

**MP044 Distributions and potential ecological impacts of organic chemicals, metals, and metalloid in water and sediment from the Geum River Estuary, Korea**

*S. Yoon, Seoul National University; S. Hong, Chungnam National University / Department of Ocean Environmental Sciences; B. Kwon, Seoul National University / School of Earth and Environmental Sciences; C. Lee, Myongji University; J. Nam, Korea Maritime Institute; J. Khim, Seoul National University / School of Earth and Environmental Sciences*

The Geum River Estuary (GRE) has been subjected to drastic environmental changes, including a dike construction and development of industrial complexes during the past 30 years. But, information on the spatiotemporal contaminations of seawater and sediment is not well known. In this study; i) distributions and sources of trace organic chemicals (TOrCs) including 24 polycyclic aromatic hydrocarbons (PAHs) and 6 alkylphenols (APs), ii) distributions of metals and metalloid, and iii) key environmental factors controlling the pelagic and benthic community structures were determined in GRE. A total of 113 seawater and 97 surface sediments were collected from the estuarine area in 2014 to 2015. Target PAHs and APs were detected in all sites and their concentrations significantly varied depending on the geological location. Although the concentrations of PAHs and APs were generally less than the suggested quality guidelines (Canada), great APs concentrations in seawater exceeding corresponding quality guidelines were detected in the inner estuary. Grass, biomass, and coal combustion were found to be the major PAHs sources and fresh input of octylphenols was identified, suggesting that industrial complexes continued to be the major sources of PAHs and APs in the given environment. The distributions of metals and metalloid were relatively high in the sediment of the inner estuary, while similar in the corresponding water column. The concentrations of metals and metalloid were generally less than corresponding guidelines (NOAA and CCME), but concentrations of some metals in sediment exceeded the Interim Sediment Quality Guidelines (ISQG, Canada). In aspect of community responses, TOrCs, metals, and metalloid in sediment, except mercury, were significantly correlated with the index of macrofaunal richness ($r$ = -0.34 -0.50, $p < 0.01$) in negative manner but with dominance ($r = 0.20$ 0.25, $p < 0.05$ or $r = 0.29$ 0.38, $p < 0.01$) of macrozoobenthos community in positive manner, respectively. These results indicated that lesser concentrations of TOrCs, metals, and metalloid could affect the community structure of macrozoobenthos. Whilst, there was no significant association with the plankton community. Overall, this research provides useful information about the contamination level, sources, and potential ecological impacts of water and sedimentary contaminants in the one representative estuarine area of the Geum River.

**MP045 Bioaccumulation Characteristics of Polycyclic Aromatic Hydrocarbons by *Mactra veneriformis* exposed to Oil-suspended Particulate Matter Aggregates**

*J. Noh, H. Kim, Seoul National University; C. Lee, Seoul National University / School of Earth and Environmental Sciences; S. Yoon, Seoul National University; S. Chu, Seoul National University / School of Earth and Environmental Sciences; B. Kwon, Seoul National University / School of Earth and Environmental Sciences / Research Institute of Oceanography; J. Ryu, Anyang University / Department of Marine Biotechnology; J. Kim, H. Lee, Korea University; U. Yim, Korea Institute of Ocean Science and Technology / Oil & POPs Research Group; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences and Toxicology Centre; J. Khim, Seoul National University / School of Earth and Environmental Sciences*

Dispersion and biodegradation of spilled oil are greatly enhanced by formation of oil-suspended particulate matter aggregates (OSAs), but little is known for impacts of OSAs on benthic invertebrates or microbial communities. In this study, followings were assessed: (1) bioaccumulation characteristics of polycyclic aromatic hydrocarbons (PAHs) by bivalvia, *Mactra veneriformis* and (2) relative abundances of microbes in sediments, during long-term feeding of OSAs. Concentrations of PAHs increased rapidly during the first week of OSAs exposure, peaked at Day 30, then declined until the end of the period of exposure. Patterns of PAHs bioaccumulation by *M. veneriformis* varied among PAHs compounds: two representative patterns were identified, one group for which bioaccumulation was constant, the other that rapidly increased up to peak then turned to decrease. Bioaccumulation of PAHs by *M. veneriformis* was dependent on changes in relative abundance of Gammaproteobacteria, reflecting active degradations of PAHs by selected genus. Four key genus included; *Porticoccus*, *Cycloclasticus*, *Alcanivorax*, and *Alkalimarinus*. These results are the first to demonstrate community-level interactions that can be considered and applicable to the use of OSAs for cleanup of spilled oil.

**MP046 Ecological Risk Assessment of Total Petroleum Hydrocarbon (TPH) Mixtures – ITRC Guidance**

*U.K. Vedagiri, AECOM / Design and Consulting; S. Alexander, Georgia Environmental Protection Division; A.S. Bess, Chevron Energy Technology Company / Environmental Unit; B. Bjorkman, GEI Consultants, Inc; J.E. Naile, Shell Oil Company / Ecosystems Research Division; M. Pattanayek, Integral Consulting Inc.; D. Rigg, ARCADIS; R. Steenson, California EPA – SF Bay Water Board; L. Trumbull, OBrien & Gere; T. Booze, California Department of Toxic Substances Control; M. Kwiecinski, Colorado Department of Labor and Employment / Division of Oil and Public Safety; R. Thun, GHD*

This presentation will provide an overview and decision-making process for addressing ecological risk from complex TPH mixtures that often function as both physical and chemical stressors to ecological receptors. The Interstate Technology and Regulatory Commission (ITRC) has developed a guidance document for risk evaluation of total petroleum hydrocarbons (TPH). While TPH are widely distributed in the environment, there is currently no comprehensive or systematic guidance at the national or state level to evaluate ecological risks associated with TPH. A systematic and comprehensive approach to identifying the TPH chemicals of potential ecological concern (COPECs) is presented in the guidance, by considering COPECs on the basis of origin, composition and environmental behavior. Sources and methods for development of screening values and toxicity reference values and several options for risk characterization are presented. A discussion of strengths, limitations and uncertainties for both mechanistic models and empirical data-based approaches will be presented with examples and case studies. This document will be the first comprehensive presentation of ecological risk assessment methods for TPH chemicals and will be released to the public in late 2018.

**MP047 Assessing the effects of environmentally relevant concentrations of antidepressant mixtures to fathead minnows exposed over a full life cycle**

*J. Parrott, Environment and Climate Change Canada / Aquatic Contaminants Research Division; C.D. Metcalfe, Trent University / Water Quality Centre*

Antidepressant drugs have been detected in municipal wastewater effluents (MWWEs) at ng/L to low µg/L concentrations. To assess the potential of these compounds to affect the survival, development and reproductive capacity of fish, we exposed fathead minnow (*Pimephales promelas*) over a full lifecycle in a flow-through system to a mixture of five antidepressants at nominal concentrations that have been detected in an Ontario MWWE; that is, venlafaxine at 2,400 ng/L, citalopram at 240 ng/L, fluoxetine at 90 ng/L, sertraline at 20 ng/L, and bupropion at 90 ng/L. In addition to exposure to this 1x AntiD Mix, we also exposed minnows to 10x concentrations of these MWWE antidepressants (i.e. 10x AntiD Mix). Mean measured concentrations of venlafaxine, citalopram, fluoxetine, sertraline, and bupropion were 2,300, 160, 110, 7 ng/L, and below detection limits, respectively, for the 5 compounds in the 1x AntiD Mix, and 33,000, 2,900, 1,000, 210, and 100 ng/L, respectively, for the compounds in the 10x AntiD Mix. During the full life-cycle exposure period of 167-168 d, no significant changes were observed in survival of fathead minnows. When male fish from the exposed treatments reached maturity, their somatic weights were increased and secondary sex characteristics were enhanced compared to control males. There were no significant differences relative to controls in condition factor, gonadosomatic index, or liver-somatic index in the exposed fish. Exposed fathead minnows produced similar numbers of eggs as control fish. There were no changes in nest-defense behaviours of male minnows that were exposed to the antidepressant mixtures. Egg quality, % fertilization, and % hatching in F1 fry were unaffected by exposure to the antidepressants. Eggs hatched 0.5 d earlier, deformities in fry were 50% lower, and there were transient decreases in length of F1 larvae at 8 dph in offspring from the treatment with the 10x AntiD Mix in comparison to controls. Overall, exposure to the antidepressant mixture at environmentally relevant concentrations (i.e. 1x AntiD Mix) caused no adverse effects in fathead minnows. Exposure to the 10x AntiD Mix increased the weight of adult male minnows and caused subtle effects in F1 offspring. This study is the first to assess sublethal effects in fish exposed to mixtures of antidepressants over a full lifecycle.

**MP048 Effects of imidacloprid to *Oreochromis niloticus* in mixtures with a pyrethroid or an organophosphate insecticide**

*P.B. Asanga Fai, Y.J. Tala Towa, University of Dschang / Department of Animal Biology*

Pyrethroid insecticides have been used for more than 20 years worldwide to control a variety of insect pests in different settings. Neonicotinoids are a new insecticide class which are important to agriculture because of their activity against sucking insects and some Heteroptera, Coleoptera and Lepidoptera. These pesticides have been detected in a variety of environmental samples and therefore there is significant concern about their potential toxic effects on non-target organisms. Interactions of components in a mixture can cause complex and substantial changes in the apparent properties of its constituents which may result in risk underestimations if only the individual toxicities are considered. We conducted this study to determine the effects of Imidacloprid and Cypermethrin mixtures on *Oreochromis niloticus* fingerlings. Mixture toxicity tests were carried out following a composite experimental design which combines aspects of the n·n design and Ray design for covering any possible interactions at various mixture ratios. Cypermethrin was found to be 6103 times more toxic than Imidacloprid. Our results also showed dose-dependent effects where at environmentally relevant concentrations greater than additive effects were observed while at higher concentrations, antagonism occurred. We conclude that concentration addition may not be an appropriate model for risk assessment of these mixtures as effects may be underestimated.

**MP049 Up a Creek Without a Fin: Applying Bioeffects Tools to Investigate Fish Fin Erosion in an Industrial Effluent Impacted Freshwater Stream**

*B.R. Blackwell, USEPA / ORD / National Health and Environmental Effects Research Laboratory; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; C. Blanksma, Badger Technical Services; J.E. Cavallin, Badger Technical Services / National Health and Environmental Effects Research Laboratory; K. Dean, Oak Ridge Institute for Science Education at USEPA; K.M. Jensen, USEPA / Mid-Continent Ecology Division; M. Kahl, S. Poole, USEPA / National Health and Environmental Effects Research Laboratory; C. Tilton, Oak Ridge Institute for Science Education at USEPA; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory*

Fish surveys in Newton Creek, a small tributary of Lake Superior, identified abnormalities in resident fish in 2016-17. The primary observation of fin loss or fin erosion could not be readily attributed to known chemical agents. This tributary receives finished industrial effluent, which contributes a complex mixture of chemicals to the system. Bioeffects-based approaches were employed at the creek to elucidate perturbed biological pathways and potential causative chemicals. Caged fathead minnows (*Pimephales promelas*) were deployed for 14 days at two sites along the creek near the effluent source ($21^{st}$ St) and further downstream ($3^{rd}$ St), and at a nearby creek not receiving finished effluent (Faxon Creek). Following in situ exposure, phenotypic responses such as fin abnormalities were recorded and tissues (plasma, liver, gonad, fin clips) collected for biochemical and gene expression analysis. A composite water sampler was deployed in parallel with caged fish to collect an integrated sample representative of the full exposure period. Composite samples were used for chemical characterization (metals, PAHs, total hydrocarbons) and for biological characterization using a number of cell-based bioassays. Caged fish showed sex-specific mortality following 14 d exposure, with full female survival at all sites but male survival reduced by 17% at Faxon Creek and 42% at $3^{rd}$ St. No mortality was observed at the $21^{st}$ St site. Site specific fin erosion was noted, though not to the extent previously observed in resident fish, with the highest occurrence observed in females at $21^{st}$ St. Initial screening of site water using a multiplexed bioassay indicated potential perturbation of a number of biological pathways including aryl hydrocarbon receptor, estrogen receptor, peroxisome proliferator-activated receptors, retinoid X receptor, constitutive androstane receptor, and pregnane X receptor. Chemical and biological results will be discussed as they pertain to potential contributions to observed fin erosion in resident fish. *The contents of this abstract neither constitute, nor necessarily reflect, official USEPA policy.*

**MP050 Environmental exposure to an urban wastewater effluent: Effects on lipid metabolism of northern pike**

*C. Depatie, University of Quebec / Department of Biological Sciences; M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Verreault, Université du Québec à Montréal / Sciences Biologiques*

Municipal effluents are composed of a complex mixture of biological and chemical substances that can represent toxicological risks for environmentally exposed fish. The Montreal Metropolitan Community (MMC) (QC, Canada) discharges on a daily basis about 2.5 million $m^3$ of primary treated wastewater in the St. Lawrence River. The MMC effluent is known to be one of the major sources of halogenated flame retardants (HFRs) in this vulnerable freshwater ecosystem. A recent study reported that exposure to this effluent can perturb the energy metabolism of the predatory northern pike (*Esox lucius*) via alteration of liver enzymes involved in fatty acid synthesis and oxidation. The present study aimed to investigate the effects of environmental exposure of pike to the MMC effluent on their lipid metabolism using a metabolomic approach targeting 175 lipid-related compounds. Concentrations of HFRs in liver of pike were used as marker of exposure to the MMC effluent. Results showed that lower concentrations of lysophosphatidylcholines (LysoPC) and higher concentrations of phosphatidylcholines (PC) were found in pike exposed to the effluent. Negative correlations were found in pike between the ratio of phospholipid classes (LysoPC/PC) and the sum of polybrominated diphenyl ethers (PBDEs). Transcriptional analyses of genes involved in the synthesis and remodeling of phospholipids including phospholipases and lysophosphatidylcholine acyltransferases (*LPCAT*) are underway to better understand the modes of action and effects of primary urban effluent exposure on lipid metabolism in fish.

**MP052 Generalized concentration addition mixtures model predicts glucocorticoid receptor activation by environmental full and partial agonists**

*E. Medlock Kakaley, USEPA/UNC Cooperative / Dept of Biological Sciences / Environmental and Molecular Toxicology Program; M.C. Cardon, E. Gray, P. Hartig, USEPA / ORD / NHEERL / Toxicity Assessment Division; V.S. Wilson, USEPA / Reproductive Toxicology Branch*

Endocrine disrupting compounds are pervasive in surface and waste waters worldwide. We, and others, have detected complex mixtures of glucocorticoid receptor (GR) agonists using both chemical analysis and non-targeted effects-based methods in recent water quality surveys. Although the GR is ubiquitously expressed throughout tissues of aquatic species and has been implicated in growth, reproduction, metabolism, and osmoregulation, the way in which a mixture contributes to a single biological endpoint remains unknown. Therefore, we characterized environmentally relevant GR agonists using a CV1 cell line transcriptional activation assay. Cells were treated with individual GR ligands, a fixed ratio mixture of full and partial agonists, or using a two-chemical matrix design with full and partial agonists. Individual agonist efficacy (full vs. partial agonism) varied and potency ($EC_{50}$) ranged over several orders of magnitude, 48.09 to 102.5% and 1.278 x $10^{-10}$ to 3.93 x $10^{-8}$ M, respectfully. Concentration addition (CA) and response addition (RA) mixture models predicted concentration response curves within the observed 95% prediction interval bands ($EC_{50(OBS)}$ = 2.341e-10 M, 95% CI 2.114e-10 to 2.598e-10 M) for an equipotent mixture of 12 full agonists. However, for equipotent mixtures containing partial agonists (21-hydroxyprogesterone or corticosterone), the observed maximum efficacies were significantly lower than the CA and RA model-predicted maximum efficacies. Therefore, the generalized concentration addition (GCA) mixtures model, which accounts for agonists with < 100% reference agonist efficacy, was applied to predict non-equipotent mixtures containing full and partial GR agonists. The GCA modeled responses of matrix exposures for partial agonist + full agonist, and full agonist + full agonist, mixtures were identified as part of the same distribution as observed responses ($p < 0.05$). The GCA model resulted in the best overall fit for mixtures containing both full and/or partial GR agonists compared to the models without efficacy variables. Elucidating the mechanistic basis of GR activation by environmental ligands will not only aid in characterizing environmental mixture samples using this effects-based approach, but will also provide a foundation for future studies in predicting and interpreting potential phenotypic adverse outcomes when the approach is applied as a chemical screening tool. *Abstract does not necessarily reflect USEPA views or policy.*

**MP053 Effects-based monitoring of bioactive contaminants associated with exposure to wastewater treatment plant discharge on the Colorado River**

*J.E. Cavallin, Badger Technical Services / National Health and Environmental Effects Research Laboratory; W.A. Battaglin, USGS / CO Water Science Center; J. Beihoffer, USEPA / NEIC; B.R. Blackwell, USEPA / ORD / National Health and Environmental Effects Research Laboratory; P.M. Bradley, USGS / South Atlantic Water Science Center; D. Ekman, USEPA / National Exposure Research Laboratory; J. Kinsey, K.A. Keteles, E. Lai, USEPA; R. Weissinger, National Park Service / Northern Colorado Plateau Network; D. Winkelman, Colorado State University / Fish, Wildlife, and Conservation Biology; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory*

Over the last several years, chemical monitoring of the Colorado River near Moab, UT, has detected a variety of chemicals of emerging concern (CECs). However, given the lack of available effects data for most of the compounds detected, potential ecological risks, if any, associated with these contaminants are unclear. To help address this question, extracts of surface water samples were analyzed using a multiplexed in vitro bioassay that evaluated activity with regard to human nuclear receptors and related transcription factors. Estrogen receptor (ER), glucocorticoid receptor (GR), and peroxisome proliferator activated receptor (PPAR) activities were associated with surface water near the Moab wastewater treatment plant (WWTP). In vitro ER activation was also confirmed in surface water near the WWTP outflow using the estrogen-responsive T47D-Kbluc bioassay. To evaluate the potential bioavailability and significance of these biologically-active contaminants, adult fathead minnows (*Pimephales promelas*) were caged at five sites along the Colorado River near Moab, UT, at various proximities to the WWTP. After four days of exposure, skin mucus, plasma, livers, and gonads were collected for measurement of a variety of biological endpoints (e.g., transcriptomics, metabolomics, steroid concentrations). An autosampler was simultaneously deployed to collect a composited surface water sample reflective of the four-day fish exposure. Composite water samples were analyzed for a suite of pharmaceuticals, pesticides, steroid hormones, wastewater indicators, and in vitro biological activities (e.g., ER, GR, and PPAR activities). Consistent with previous monitoring, total estrogenic activity of surface water was confirmed using the T47D-Kbluc bioassay, with approximately 45 ng/L of 17β-estradiol equivalents (E2-EQ) estimated at the WWTP discharge site and 2 ng/L E2-EQ at the proximal downstream site. Consistent with downstream dilution of estrogenic activity, no statistically significant differences were observed in male liver vitellogenin mRNA expression among any of the sites, excluding the WWTP site in which 100% mortality was observed. Results suggest rapid dilution of biologically-active contaminants downstream of the WWTP discharge and will be discussed relative to the potential effects of CECs in the Colorado River. *The contents of this abstract neither constitute nor reflect USEPA policy.*

**MP054 The Enigmatic Disappearance of the Once-common Leopard Frogs from Long Island: Are contaminants to blame?**

*L. Lockett, Rutgers University / Department of Ecology Evolution and Natural Resources; J. Feinberg, Smithsonian Conservation Biology Institute; J.B. Belden, Oklahoma State University / Integrative Biology; J. Burger, Rutgers University*

Globally, amphibians are in decline, and in some populations, declines have been attributed to the presence of pesticides and other contaminants in the environment. Relatively few toxicological studies focus on bioaccumulation of such contaminants in amphibian tissue, likely because such studies on amphibians are not required by the federal government. However, knowledge of the bioaccumulation of these toxicants could inform local agencies and concerned citizens as to which toxicants require additional regulation and restriction to protect threatened and endangered amphibian populations. We hypothesized that profiles of bioaccumulated pesticides and other non-metallic contaminants would differ between a site where leopard frogs are present in central New Jersey (NJ) and other sites where leopard frogs are now extirpated on Long Island (LI), New

York. The objectives of this study were to determine (1) detectable toxicant levels in amphibian tissues sampled from NJ and LI, and (2) whether the extirpation of leopard frogs from LI can be explained by differences in contaminant detection between rural parts of LI and NJ. We examined southern leopard frog tadpoles (Rana sphenocephala) from NJ and a combination of enclosure-raised southern leopard frog tadpoles and wild-collected green frog (*Rana clamitans*) and bullfrog (*Rana catesbeiana*) tadpoles from LI. Tadpoles were homogenized in groups for each replicate sampling. Gas chromatography/mass spectrometry (GCMS) was used to detect the 73 most widely detected and distributed contaminants in New Jersey and New York regions of the United States, and a PCA analysis was used to determine the most predictive contaminants. We found that many chemicals commonly detected in freshwater aquatic habitats were not present at detectable levels in our samples. Polycyclic aromatic hydrocarbons were the most prevalent class of toxicants found in all frog tissue samples and were statistically significant in the PCA analysis. All frog tissue samples contained fluoranthene, PCB52, and PCB118. Although sites were similar in their chemical profiles, the leopard frog site had lower levels of DDE, DDD and phenanathrene when compared to non-leopard frog sites. Pesticides alone do not explain the absence of leopard frogs from sites in LI. Future studies should compare a larger number of habitats that continue to support the leopard frog and habitats from which this species has been extirpated.

### MP055 Bioaccumulation of butyltins in marine environment and their impacts on intertidal benthic community

*T. Kim, Seoul National University; S. Hong, Chungnam National University / Department of Ocean Environmental Sciences; S. Song, B. Kwon, Seoul National University / School of Earth and Environmental Sciences & Research Institute of Oceanography; J. Ryu, Anyang University / Department of Marine Biotechnology; J. Khim, Seoul National University / School of Earth and Environmental Sciences*

Thirteen years ago, the Korean Government introduced a regulation prohibiting the use of tributyltin (TBT), which was a component of antifouling paints. A subsequent decline in the concentrations of butyltins (BTs) was recorded in seawater and sediment, however, the current concentrations of BTs in biota have not been well documented. The spatiotemporal distributions and concentrations of BTs were recorded in biota from 2013 to 2015 along the coasts of Samcheok and Tongyeong using GS/MSD analysis. Crustaceans contained the greatest concentrations of BTs, followed by gastropods, fishes, and bivalves. We found that the concentrations of BTs were relatively greater at Tongyeong compared to those in Samcheok, primarily because of the geographical characteristics of the area. We also confirmed that the regulation has been effective by showing that the TBT concentration decreased over the 3-year study period. The TBT concentrations of gastropods and bivalves fell within the limits of the guidelines and/or the effective concentration of the toxicological endpoint reported previously. The concentrations of BTs also varied among species, being dependent on the weight of the soft tissue. Furthermore, the greater quantities of BTs degradation products compared to TBT confirmed the absence of recent inputs of the very pollutants during the study periods. We investigated the benthic community in the study area for estimating butyltins' impacts on the benthic community. We found butyltins degradation index was significantly related with several ecological indices ($p < 0.05$). However, compared to other Asian countries, biota BTs were greater in Korea, with noticeably greater concentrations along the south coast. Thus, further investigation of the distributions of BTs along the Korean coasts would be timely required. In conclusion, our results provide useful background information about the recent trends of BTs in Korea.

### MP056 *Microcystis aeruginosa* adversely impacts *Daphnia* spp.: Implications on food webs in the Great Lakes

*R.S. Shahmohamadloo, University of Guelph / School of Environmental Sciences; D.G. Poirier, Ontario Ministry of the Environment / Laboratory Services Branch; X. Ortiz Almirall, Ministry of Environment and Climate Change of Ontario / Laboratory Services Branch; S. Bhavsar, Ontario Ministry of the Environment and Climate Change; P.K. Sibley, University of Guelph / School of Environmental Sciences*

Harmful algal blooms dominated by *Microcystis* are a troublesome nuisance to freshwater ecosystems used for drinking, irrigation, fishing, and recreational purposes. Many *Microcystis* blooms produce strains of the hepatotoxin microcystin that is capable of inflicting harm to zooplankton. Research on the effect of microcystins on zooplankton remains elusive; from one perspective, studies suggest *Daphnia* can be used to suppress phytoplankton, including cyanobacteria, and coexist in toxic blooms; however, studies have also indicated toxic effects on *Daphnia* that consume cell-bound microcystin. This dual perspective may be attributable to an evolutionary adaptation in *Daphnia* that ensures survival and reproduction in toxic cyanobacterial blooms. We examined reproduction and survival of laboratory-cultured *Ceriodaphnia dubia* and *Daphnia magna* in microcystin-producing *Microcystis aeruginosa* through a series of life-cycle bioassays. Test organisms were exposed to a concentration gradient ranging from 0.5 µg/L to 100 µg/L microcystin-LR which corresponds to values typically found in the Great Lakes during bloom season. Mortality was observed in *C. dubia* ($LC_{50}$ = 2 µg/L) and *D. magna* ($LC_{50}$ = 37 µg/L) exposed to microcystin-LR, and reproductive effects at concentrations as low as 2.5 µg/L. This information will improve our understanding of the risks posed to food webs in the Great Lakes.

### MP058 Acute sub-lethal and lethal toxicities of elevated $CO_2$ on various stages of marine medaka *Oryzias melastigma*

*C. Lee, Seoul National University / School of Earth and Environmental Sciences; B. Kwon, Seoul National University / School of Earth and Environmental Sciences & Research Institute of Oceanography; S. Hong, Chungnam National University / Department of Ocean Environmental Sciences; J. Noh, Seoul National University / School of Earth and Environmental Sciences & Research Institute of Oceanography; J. Lee, Seoul National University; J. Ryu, Anyang University / Department of Marine Biotechnology; S. Kang, Korea Research Institute of Ships and Ocean Engineering / Offshore CCS Research Unit; J. Khim, Seoul National University / School of Earth and Environmental Sciences*

The potential leakage from marine $CO_2$ storage sites is of increasing concern, but few studies have evaluated the probable adverse effects on marine organisms. Fish, one of the top predators in marine environments, should be an essential representative species used for water column toxicity testing in response to waterborne $CO_2$ exposure. In the present study, we conducted fish life cycle toxicity tests to fully elucidate $CO_2$ toxicity mechanism effects. We tested sub-lethal and lethal toxicities of elevated $CO_2$ concentrations on marine medaka (*Oryzias melastigma*) at different developmental stages. At each developmental stage, the test species was exposed to varying concentrations of gaseous $CO_2$ (control air, 5%, 10%, 20%, and 30%), with 96 h of exposure at 0–4 d (early stage), 4–8 d (middle stage), and 8–12 d (late stage). Sub-lethal and lethal effects, including early developmental delays, cardiac edema, tail abnormalities, abnormal pigmentation, and mortality were monitored daily during the 14 d exposure period. At the embryonic stage, significant sub-lethal and lethal effects were observed at pH < 6.30. Hypercapnia can cause long-term and/or delayed developmental embryonic problems, even after transfer back to clean seawater. At fish juvenile and adult stages, significant mortality was observed at pH < 5.70, indicating elevated $CO_2$ exposure might cause various adverse effects, even during short-term exposure periods. It should be noted the early embryonic stage was found more sensitive to $CO_2$ exposure than other developmental stages of the fish life cycle. Overall, the present study provided baseline information for potential adverse effects of high $CO_2$ concentration exposure on fish developmental processes at different life cycle stages in marine ecosystems.

**MP059 Development of a juvenile fathead minnow fin regeneration assay for use in evaluating chemical involvement in fin regeneration impairment**

*C. Tilton, USEPA / ORD; C. Blanksma, Badger Technical Services; J.E. Cavallin, Badger Technical Services / National Health and Environmental Effects Research Laboratory; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; J. Swintek, Badger Technical Services; K.M. Jensen, USEPA / Mid-Continent Ecology Division; M. Kahl, D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory*

Teleost fish are among the few vertebrates with the ability to nearly perfectly regenerate an amputated or damaged limb (i.e., fins). Fin damage can result from a wide range of natural sources including abrasive habitat surfaces, predation, conspecific aggression, and nutritional deficiencies. However, increased incidence of fin erosion has also been observed at sites impacted by a wide range of pollutants including pulp mill effluents, coal-ash runoff, oil sands process waters, etc. This suggests that exposure to certain chemical contaminants may impair the processes that support fin regeneration and repair. Development of a laboratory-based fin regeneration assay would have utility for both testing this hypothesis, as well as screening of both individual chemicals and complex mixtures for their ability to impair fin regeneration processes. The present study reports on the time-course of fin regeneration in 30 d posthatch fathead minnows (*Pimephales promelas*) following partial caudal fin amputation. Fish were sampled daily from 0-7 days post amputation (dpa). Fish length, caudal fin area, and specific fin ray lengths were measured at each time point using image analysis. Additionally, RNA was extracted from caudal fin samples and expression of several genes known to play a role in fin regeneration, including fibroblast growth factor receptor 1a (fgfr1a), lysyl hydroxylase (lhl1) and patched-1 (ptch1), was evaluated using quantitative polymerase chain reaction (qPCR). Based on averaged fin ray length and/or fin area as determinants, statistically significant regrowth was detectable by 4-5 dpa (25° C). Both ptch1 and lhl1 expression was significantly increased at 3 dpa compared to unclipped controls, suggesting these as potential molecular markers of the initiation of fin regrowth. A statistical power analysis focused on the phenotypic measurements of fin regrowth suggest that a sample size of n=10 measured at 7 dpa would likely be statistically robust for detecting treatment effects on regeneration. Results inform development of a standardized test that can be used for routine screening. *The contents of this abstract neither constitute, nor necessarily reflect, USEPA policy.*

## Deep Learning for Predictive Toxicology

**MP060 QSAR Modeling for Predicting the Inhibitory Concentration (IC50) of Organophosphates for Human Acetylcholinesterase**

*A. Ranjan, A. Chauhan, T. Jindal, Amity University / Amity Institute of Environmental Toxicology, Safety and Management*

Organophosphates (OP) are broad-spectrum insecticide and nerve agents which is majorly used in agriculture in India. OP is diverse category of molecules with varying functional groups which contribute their physical and chemical properties. Most of our knowledge about OP and their toxicity or pharmacodynamics/pharmacokinetics is based upon laboratory animals. Therefore, when it comes to combat OP poisoning in human, we are forced to rely upon these research data. In this research we have developed a QSAR model which could predict the inhibitory activity ($IC_{50}$) of OP against human AChE. The tool used for QSAR model was Easy QSAR 1.0 and activity chosen was $IC_{50}$ of OP against human AChE. Molecular weight (weight), H-bond acceptor (HbondAccp), Gutman molecular topological index based on valence vertex degree(log10) (GMVTIV), logP, number of ratable bonds (nrot), number of aromatic bonds (naro), topological polar surface area (TPSA) and weiner Index(W) are the eight descriptors used to build the models. Four sorting methods were used namely: random, ascending order of inhibitory activity, ascending order of molecular weight and ascending order of TPSA and each sorted list was divided by three methods: "50-50", "Alternate and 50-50" and 60-40. Each training set was validated before validating the test set. The best QSAR model obtained was having $R^2$ of 96.9 and Adj. $R^2$ was 96.4 (test set validation) with combination of sorted list "ascending order of TPSA" and division 60-40. The resulting model has $R^2$ 90.4 and Adj. $R^2$ 89.5 while validating the training set. This model has -0.53 of bias and 0.63 RMSD. All statistical calculation was done using Minitab and MS excel. The study infers that a QSAR model has been developed which can efficiently predict the $IC_{50}$ of the OP compounds for human AChE.

**MP061 The effects of ionizing radiation on mutation rates: A meta-analysis**

*Y. Loera, A. Bonisoli-Alquati, California State Polytechnic University, Pomona / Biology*

The effects of low-dose ionizing radiation from environmental contamination on mutation rates vary throughout the literature. A comprehensive view of these effects have yet to be determined, as studies vary greatly in their experimental design, level and type of contamination, and the organisms on which effects are tested. To characterize when ionizing radiation causes an increase in mutation rate, we conducted a meta-analysis of the published literature. We classified studies based on the methods of detecting mutation rates (or endpoint), source of radiation contamination, and taxonomic group. The effects were determined for each study by extracting and converting statistics to the same effect size, Fisher's transformed Pearson correlation (Zr). We included 112 studies, with a total of 282 estimates of effect. Overall, data show an increase in mutation rates due to ionizing radiation. An analysis of variance showed that extensive variation existed among studies according to their endpoint used, type of radiation contamination, and taxonomic group. Large effect sizes were observed in studies of chromosomal aberrations, following nuclear accidents, and in organisms other than mammals. Our findings point to chromosomal aberration as a sensitive method for detection of changes in mutation rate induced by ionizing radiation, and possibly other environmental mutagens. The analysis of the effects of ionizing radiation plays a large role in understanding and mitigating damages following radioactive contamination. It is also useful in understanding natural variation in susceptibility to ionizing radiation and other mutagens, under different contamination scenarios.

**MP062 Quantitative Target-specific Toxicity Prediction Modeling: A Novel Predictive Toxicology Approach**

*P. Gong, S. Thangapandian, U.S. Army Engineer Research and Development Center / Environmental Lab; G. Idakwo, C. Zhang, University of Southern Mississippi / School of Computing*

Quantitative structure-activity relationship (QSAR) modelling is a chemical descriptors-based approach for quantitative prediction of biological activity, potency or toxicity of a chemical. QSAR modelling may suffer low prediction accuracy in the absence of information on chemical-biomacromolecule interactions. In order to mitigate this problem, we developed a novel Quantitative Target-specific Toxicity Prediction Modeling (QTTPM) approach that integrated molecular dynamics (MD) simulation and machine learning. As a proof-of-concept study, we chose androgen receptor (AR) as the toxicant-targeted biomacromolecule because AR is a nuclear receptor playing crucial roles in the development of male reproductive system and tumors in prostate, bladder, liver, kidney and lung. Molecular docking and MD simulations were employed to generate a new set of dynamic protein-ligand interaction descriptors (dyPLIDs) used for developing QTTPMs. We selected 274 chemicals (154 agonists/120 antagonists) with quantitative AR assay outcomes from Tox21 datasets. First, we performed five 100-ns MD simulations of AR crystal structures in its un-bound (*apo*), two agonist-bound (testosterone and dihydrotestostrone), and two antagonist-bound (R-bicalutamide and cyproterone acetate) forms and identified key interaction patterns leading to >400 dyPLIDs. Second, 6-ns MD simulations of 274 AR-ligand docked complexes were performed to calculate dyPLIDs. Third, Random Forest (RF) algorithm was deployed to identify key descriptors (including both

conventional 1D/2D/3D descriptors and dyPLIDs). Fourth, QTTPMs were built using the key descriptors and AR assay data. QTTPMs demonstrated superior accuracy than QSAR models constructed with conventional chemical descriptors. In addition, QTTPMs provided insights of key protein structural changes upon ligand binding that modulated the activity of the AR. The novel QTTPM approach was developed using a small dataset of 274 AR agonists/antagonists. Although more biomacromolecular targets and chemicals warrant further investigations, this study demonstrates the superiority of QTTPM over QSAR and that QTTPM is a promising new tool for computational predictive toxicology.

**MP063 Predicting Fish Embryo Development in Videos using Convolutional Encoder and Decoder Neural Network**

*C. Lai, University of St. Thomas / Graduate Programs in Software; D. Martinovic-Weigelt, University of St. Thomas / Biology; X. Sui, University of St. Thomas / School of Engineering*

Embryo development follows a set of defined spatial and temporal patterns. If deep neural networks (DNNs) can learn those patterns from a collection of normal embryo development videos then they could predict how embryo will develop in the next few video frames (near future). Conventional DNNs have been used to learn from the past toxicology studies (training sets) and to predict possible adverse outcomes. Those approaches rely on supervised learning in which each record of the training data has a manually-assigned label that indicates the outcome of each study (i.e., toxic/non-toxic or the degree of toxicity). Because each video frame in the training videos contains large number of pixels it is not feasible to assign one label to each pixel. Hence, here we propose a novel, semi-supervised learning approach. The semi-supervised DNN trained in this study uses an encoder-decoder architecture. The encoder part of our DNN learns to compress each input video frame $F_t$ at time t into a low-dimension vector $V_t$ such that it can be used by the decoder to re-construct each video frame $F_{t+1}$ at time t+1. More specifically, the decoder learns to decompress the vector $V_t$ into an image that is as close as possible to the next video frame $F_{t+1}$. In this semi-supervised learning process, the next video frame $F_{t+1}$ is used as the learning target (outcome) for each previous video frame $F_t$, avoiding the need of assigning labels to all pixels in all video frames. A sequence of convolution layers was used in our DNN encoder to perform the convolutional operations that extract subtle patterns embedded in each video frame. Another sequence of transposed convolution layers was used in our DNN decoder to re-construct/predict the next video frame. Original and predicted embryo development outcomes (over a 6 h period) were generated and compared. The results demonstrate that our DNN is capable of closely predicting embryo morphology in the next video frame. The left side of each sub-figure in Figure 1 at https://drive.google.com/open?id=1TRAqNUHpFApQ-pLmIZNTwCHvhYFwZj7L shows the original video frame at different time over a 6-hour period in a video showing zebra fish embryo development. The right side of each sub-figure in Figure 1 shows the predicted embryo development generated from our convolutional encoder-decoder DNN. The results demonstrate that our DNN is capable of closely predict the embryo's new structure in the next video frame.

**MP064 Graph wavelet neural network for toxicity prediction**

*F. Gao, S. Boyd, B. Teppen, Michigan State University / Plant, Soil and Microbial Sciences; M. Hirn, Michigan State University*

Quantitative structure activity relationship(QSAR) methods have been widely used in the toxicity prediction of organic molecules. Compared to traditional animal tests, QSAR methods are less time and cost consuming. In this study, we have developed random walk based graph wavelet scattering neural network for toxicity prediction. Graph wavelet was developed from molecule graph and was used to generate new molecule features from eight existing characteristics of molecules: atom total charges, atom valence charges, and one-hot encoding of: electron acceptor, electron donor, aromatic atoms, sp1, sp2 and sp3 hybridization. Our model was invariant to molecule permutation, translation and rotation. Multi-task learning was used to leverage additional information from different tasks. A three layer of neural network was built for training the new features and L1 regularization was used to acquire a sparse neural network and avoid overfitting. Multiple toxicity datasets were acquired from PubChem. Due to the imbalance distribution of data points among different classes in each dataset, we applied data augmentation by adding random noises to existing data points to create a larger database for neural network training. In each task, we combined 80% of data points from each category for training, 10% from each category for validation and 10% for test. Our model achieved state-of-art test accuracy on multiple datasets. The results indicated that our graph wavelet neural network models can be successfully used for toxicity predictions.

**MP065 Predicting Potential Adverse Outcome Pathways using Long-Short Term Memory (LSTM) Neural Network**

*C. Lai, University of St. Thomas / Graduate Programs in Software; X. Sui, University of St. Thomas / School of Engineering; D. Martinovic-Weigelt, University of St. Thomas / Biology*

Adverse outcome pathways (AOPs) organize relationships among initial chemical-biological interactions, intermediary key events, and adverse outcomes (AOs) relevant to risk assessment. AOPs have potential to support and enhance the use of mechanistic data in regulatory decision-making, but efficient ways of AOP development are lacking. Here we explore potential of training deep neural networks (DNNs) to absorb complex knowledge from large toxicology databases, and to predict potential AOPs. Because each AOP contains a sequence of causal entities, the task of predicting AOPs requires a special type of DNNs that can learn such sequentially causative relationships. For this study, a type of DNN known as the *Long-Short Term Memory* (LSTM) neural network was adapted and utilized. In this approach the prediction depends on, not just the most recent input, but also the learned weights of all the previous inputs. This LSTM capability is extremely useful in assessing the importance of causative relationships among previous AOP entities for predicting the next causative event or adverse outcome. While the LSTM architecture was designed to capture the relationships among sequential inputs, extensive training is essential for LSTM to grasp the causative relationships among so many AOP entities. We collected hundreds of millions of relationships among millions of concepts (including genes, chemicals, proteins, diseases) from various sources like Comparative Toxicogenomics Database (CTD), ToxCast Dashboard, Unified Medical Language Systems, 16-million abstracts of PubMed papers, and AOP Wiki. Since all the relationships were text in the data sources, they were first translated into 300-dimension vectors by another word-embedding neural network before inputting to our LSTM for training. To demonstrate the utility of above approach we first examined two sample predictions generated from our LSTM that was trained by using pairs of 104,194 relationships extracted from the CTD database. For each sample, when user presented a causal relationships between a chemical and an impacted gene, our trained LSTM predicted the top two possible AOs. Our results shows that the predicted AOs were very similar (i.e. drug induced liver injury) to the AOs recorded in the CTD database (i.e. fatty liver). Users can also present relationships between gene-disease or disease-chemical to our LSTM which can then predict chemical or gene, respectively.

## Bridging the Divide Between Research Scientists and Decision-Makers in Environmental Fate and Exposure Modeling

**MP066 Development of a global environmental exposure modeling framework for risk assessment of chemicals disposed down the drain: A case study for China**

*K. McDonough, P&G / Environmental Stewardship; K.E. Kapo, R. Vamshi, Waterborne Environmental, Inc.*

Environmental exposure assessment of chemicals that are disposed down the drain (such as consumer product ingredients) at the global scale within a consistent and accessible framework has remained a challenge over the years, despite advancements in exposure modeling and global and local data resources. Historically, assessment efforts have been tailored and applied to specific geographies and used simplistic approaches rather than to build a spatially resolved global assessment infrastructure. Challenges such as inconsistent, scarce, or rapidly-evolving data resources, particularly for developing countries where assessment needs are high, have further complicated the evolution of spatially resolved global exposure assessment tools. However, through strategic integration of existing global data resources and established modeling tools, a standardized framework and methodology for GIS-based exposure modeling can be developed for the global scale. In this study, we present a spatially resolved global environmental exposure model approach designed to incorporate best-available data and modeling tools, using China as a case study. The global hydrology network from HydroSHEDS and HydroBASINS (Lehner et al. 2008 and 2013), global river flow and population estimates, and best-available country-specific water use and wastewater treatment information were integrated with the GIS-ROUT exposure model (Wang et al. 2005) and iSTREEM® model framework (American Cleaning Institute) to provide a means of estimating the distribution of concentrations of a chemical disposed down the drain across a river network based on chemical production volume and consumer usage estimates. Both wastewater treatment plant effluent and direct discharge are accounted for by the model through estimation of catchment-specific emissions. The spatial nature of the model provides a robust means for estimating variability in environmental exposures. Details of the various model components and generated output for China are overviewed, as well as considerations and discussion regarding on-going extrapolation to the global scale. The framework developed as part of this model is highly adaptable to countries with an abundance of data (e.g., North America, Western Europe, etc.) or those scarce with data (e.g., developing countries) available to parametrize the model.

**MP067 Development of a spatially resolved global mean annual flow dataset for use in environmental risk assessment: A case study for China**

*R. Vamshi, Waterborne Environmental, Inc.; K. McDonough, P&G / Environmental Stewardship; K.E. Kapo, A. Ritter, Waterborne Environmental, Inc.; B. Kearns, Waterborne Environmental, Inc. / Geospatial Data Technologies*

Environmental exposure models for chemicals used widely across large geographic areas and disposed of down the drain are important tools for informing ecological risk assessments. One important element of these models is understanding the dilution of wastewater treatment plant (WWTP) effluent into the receiving stream (dilution factors) which allows for the estimation of in-stream environmental concentrations based on either estimated flow of receiving waters. In the U.S., the iSTREEM model (American Cleaning Institute) estimates dilution of WWTP effluent into receiving streams through the incorporation of a spatial hydrologic network with associated flow data (National Hydrography Dataset Plus) into the exposure model to spatially associate (and route) local WWTP emissions with corresponding local flows. A similar approach for generating localized dilution factors can be employed on the global scale to integrate the chemical emissions component of the model with a hydrologically-connected global river network with associated flow values. The HydroSHEDS and HydroBASINS datasets (Lehner et al. 2008 and 2013) provide a global hydrology dataset that can be used as a spatial hydrologic framework, including a network of streams and rivers and watershed and catchment boundaries. However, flow estimates corresponding to the global river network are a critical attribute that must still be incorporated for exposure modeling. Using China as a case study, a mean annual flow dataset to correspond with the HydroSHEDS and HydroBASINS global data was developed using the well-established Curve Number (CN) approach developed by Natural Resources Conservation Service (NRCS, USDA). The CN approach integrates environmental and landscape features including best available and high-resolution precipitation, soils, and land use characteristics to estimate surface runoff over the land area. The high-resolution runoff grid was spatially combined with hydrology datasets to derive flow estimates across a river network. Global datasets were utilized for model parameters so that the approach could be extrapolated to the global scale, while also providing the flexibility to incorporate best-available data. This presentation will provide a detailed overview of the runoff methodology, validation against measured flow data, and the resulting river flow dataset for China.

**MP068 A new tool for the toolbox: Predicting multi-pathway emission and fate of contaminants entering freshwater systems in Europe**

*C.M. Holmes, Waterborne Environmental, Inc.; J. Amos, Waterborne Environmental, Inc. / Geospatial Data Technologies; A. Ritter, W.M. Williams, Waterborne Environmental, Inc.*

Exposure models help to prospectively assess the potential for ecological exposures from releases of substances into the environment. Availability of newer data, increasing computing power and improved methods provide continuing opportunity to improve our ability to predict environmental exposures through models and add to our “toolbox”. We present a new model designed to encompass multi-pathway environmental emissions coupled with environmental fate components, contained in a modular and transparent framework which is scalable and portable to multiple geographies. This spatially-explicit model (presented here for Europe) is based on publicly available datasets, combined with a hydrologic framework containing geographically variable emissions linked to a river network simulating environmental transport via surface water. The hydrologic framework is based on a set of basins and rivers (WWF HydroSHEDs) linked to emission characteristics for each sub-basin (more than 37,000 in the EU-30). Emissions characteristics are derived from point-source wastewater data (EEA Waterbase) as well as diffuse source inputs, accounting for the potential of urban storm water runoff or other overland flow constituents. Concentrations of contaminants are routed through the river network based on local river attributes combined with assumptions about chemical fate in the aquatic environment. Multi-year, high-resolution data on river flow (FLO1K) are leveraged for an expanded set of possible modeling scenarios. Transparency is critical for model understanding and acceptance. Model documentation follows standard documentation protocol proposed by the European Committee for Standardization (CEN) as described in the 2016 CEN workshop: “*Promoting the acceptance and use of chemical exposure models through transparent documentation*”. Several scenarios will be presented covering different use/emission situations and substance fate characteristics, including the relative importance of different emission pathways (e.g., down-the-drain, urban storm water, land-based diffuse runoff) and environmental media. While the presented material is an example of environmental emission and fate of different substances, it represents a working framework implemented for Europe with viable application to other geographies.

**MP069 EPI Web Suite: Design features and enhancements for an online platform**

*W. Lee, EPA / OPPT; M. Kawa, SRC Inc. / Environmental Health Analysis; L. Cassidy, SRC Inc. / EHA; W. Meylan, SRC, Inc.*

The EPI (Estimation Programs Interface) Suite™ is a collection of physical-chemical property and environmental fate estimation programs maintained by the US Environmental Protection Agency’s (EPA) Office of Pollution Prevention and Toxics (OPPT). OPPT performs, and is responsible for, chemical hazard and risk evaluations under the Toxic Substances Control Act (TSCA), amended by the 2016 Frank R. Lautenberg Chemical Safety for the 21st Century Act. OPPT has developed estimation tools from extensive experience assessing chemicals under TSCA, including (quantitative) structure-activity relationships or (Q)SARs in EPI Suite™. Understanding the estimation methods and their appropriate application is important when running and interpreting model results. The underlying predictive methods and equations in EPI Suite™ have been published in peer-reviewed technical journals and are available in help files; however, it is also useful to convey model information to users while running the estimates in the context of a specific chemical. This presentation will discuss developments made to EPI Suite™, as a web-based platform, to increase transparency and present level of confidence information for the underlying methodologies to users. Specifically, features to facilitate interpretation of the model domain for each model's training and validation set will be highlighted. This includes an approach for displaying the chemical structures and empirical data for structural analogs using the structural fragment based recognition approach from the EPA's Analog Identification Methodology (AIM) Tool. Additionally, a demonstration of the features of the web based tool will be performed. *Disclaimer: The views expressed in this abstract are those of the authors and do not represent Agency policy or endorsement.*

**MP070 Bioavailability of Mercury in Power Plant Wastewater and Ambient River Samples: Evidence that the Regulation of Total Mercury is Not Appropriate**

*R.J. Reash, American Electric Power*

Mercury (Hg) is a neurotoxin that can cause debilitating effects to human and environmental receptors under high exposure conditions. For industrial and municipal point sources that discharge Hg, wastewater limitations on total mercury (THg) concentrations or loads are typical. While this regulatory practice provides simplicity for regulated industry and water resource agencies (re: analytical detection and reporting purposes), it ignores the important considerations of speciation and bioavailability. In this study water samples were collected from multiple power plant wastewater, simulated mixing zone, and ambient river locations (N = 10 to 20) and analyzed for bioavailable Hg (methylmercury and acid-labile mercury, or BHg) forms, THg, and dissolved Hg. The median concentration of THg in wastewater, mixing zone, and ambient river samples was 7.1, 5.3, and 2.3 ng/L, respectively. The percentage of THg as BHg (median values) were 18.7, 29.3, and 8.5% for wastewater, mixing zone, and ambient river samples. The percentages of methylmercury (MeHg) as THg were not statistically different between paired ambient and mixing zone samples ($P > 0.05$), indicating that wastewater did not increase the MeHg fraction when mixed with ambient water. Multiple regression analysis indicated that variation in THg for combined wastewater and mixing zone samples could be adequately explained by pooled water quality parameters (total suspended solids, total dissolved solids, sulfate, total organic carbon, pH, specific conductivity; $r^2 = 0.51$; $p < 0.05$), however no significant regression relationships were apparent for the percent of BHg. These results, at least for the wastewater samples evaluated, indicate that regulating THg is likely overly-conservative and mechanisms to regulate the bioavailable forms of Hg are needed. If Hg fish tissue monitoring data indicate concentrations are less than consumption thresholds, metal translator methodologies or bioavailability-based criterion techniques (as currently used for non-Hg trace elements) should be allowed for Hg.

**MP071 Chemical Hazard Screening Using GHS**

*S. Risotto, American Chemistry Council / CPTD; S. Dubrow, American Chemistry Council / Sustainability & Market Outreach; B. Howard, American Chemistry Council / Sustainability and Market Outreach*

Demand for information on the health and environmental hazards of chemicals has increased in recent years, as have calls for a transparent presentation of these data. These requests for more and more data have produced a need for sources of publicly available data and methodologies to translate that information into a form that can be readily understood and can be combined with other factors for alternative assessment. This need is particularly acute for small- and medium-sized any companies that do not have the resources to conduct extensive reviews of the scientific literature. Fortunately, the Globally Harmonized System of Classification and Labelling of Chemicals (GHS) provides a globally consistent platform for reporting human and environmental hazard information that is the basis for many of the commercial hazard screening tools. The European Chemicals Agency (ECHA) has compiled this information into an easy-to-use search tool for the vast amount of GHS information that has been submitted as part of the European Regulation on Registration, Evaluation, Authorization and Restriction of Chemicals (REACH). The ECHA site provides GHS classifications for the 20,000+ REACH-registered chemicals. In most cases, the ECHA will provide all of the GHS information submitted by REACH registrants, as well as the number of entities that provided any particular set of GHS classifications. While GHS does not include classification for persistence and bioaccumulation, Environment and Climate Change Canada (ECCC) has generated a comprehensive evaluation of the P & B characteristics of the chemicals on their Domestic Substances List (DSL). That information is available from the ECCC website. As part of its Sustainability and Market Outreach initiative, the American Chemistry Council (ACC) has collaborated with several partners to collect the GHS and P/B classifications available from ECHA and ECCC and to translate that information into a well-known and respected hazard scoring system. Such a screening device for product designers and other non-toxicologists can help to demystify the hazard assessment process and complement existing efforts to evaluate multiple criteria, including hazard, in making chemical selection decisions.

**MP072 A Tiered Approach to Chemical Screening**

*S. Dubrow, American Chemistry Council / Sustainability & Market Outreach; S. Risotto, American Chemistry Council; B. Howard, American Chemistry Council / Sustainability and Market Outreach*

In today's age of increased inquiry into the chemistry of everyday products, how do Retailers and Brands respond to requests for more rigorous product safety assessments? There are a number of Alternatives Assessment (AA) frameworks used in the marketplace today to evaluate potential substitutions for chemicals in products. Most rely on chemical lists or scoring methodologies that are based solely on a chemical's inherent hazard to screen products and alternatives. However, risk is a function of hazard; consequence; and the likelihood the consequence will occur. For hazards presented by chemicals in products, the likelihood of consequence is often dependent on whether the chemical can be released from the product, and an individual subsequently exposed to that release. A more comprehensive risk assessment generally requires more extensive data input, and can involve technical models that are complicated to use without the needed education and training. To address this issue, ACC's Sustainability and Market Outreach division developed a tiered approach to chemical screening that provides a simple, yet science-based method for evaluating the potential for chemical exposure from a product. This more holistic framework for alternatives assessment can be used to introduce the concept of risk and exposure into existing hazard-only methodologies. In addition to an initial hazard screening, this approach includes higher-level tiers to assess whether a release is likely based on chemical and product characteristics. The third tier provides a risk scoring methodology based on the intended use of the product, and the final output is a risk matrix that can be used to prioritize actions and resources towards the highest risk scenarios. ACC also recently began a project to automate this tiered approach, to facilitate understanding and use of the scoring methodology.

**MP073 A Multi-Criteria Approach to Alternatives Assessment using multi-criteria decision analysis (MCDA)**

*B. Howard, S. Dubrow, American Chemistry Council / Sustainability & Market Outreach; S. Risotto, American Chemistry Council / Chemical Products and Technology Division*

When considering alternative chemicals in product formulations, how do you consider tradeoffs between disparate factors such as performance, cost, and lifecycle impacts? Multi-criteria decision analysis (MCDA) offers an established approach for well-informed decision-making. Stakeholders throughout the value chain make decisions on products and chemicals every day – but are these decisions optimal? With an ever increasing number of criteria to evaluate—price, performance, lifecycle impacts, risk—these decisions pose a significant challenge when considering the many tradeoffs. Recently, alternatives assessment (AA) frameworks have attempted to address these complications, but often do not provide guidance for users to make specific selections. ACC's Sustainability and Market Outreach division is working to solve this issue by incorporating decision science principles into the AA methodology to help users make informed decisions tailored to their preferences. In our demonstration pilot, we use multi-criteria decision analysis (MCDA)—tucked within a user-friendly interface—to guide users as they make decisions in a scientific manner that reflects their preferences and explore tradeoffs between alternatives. ACC populated the online MCDA framework with data from two existing AA assessments: 1) the BizNGO AA for methylene chloride discussed above, and 2) Washington State Antifouling Boat Paint Alternatives Assessment Report, conducted by TechLaw and Northwest Green Chemistry (NGC). ACC also utilized data from other published sources for criteria not considered in these reports. The output is presented using data visualization tools, with the results dependent on user criteria and weightings. To-date, ACC collaborated and received positive and encouraging feedback from academic experts in the field, non-profit organizations, other trade associations, stakeholders within the value chain, and technology providers. We envision that the results of this project will provide a general platform through which stakeholders may perform screening-level assessments and consider tradeoffs for products of interest to them, or may incorporate this framework into their own methodologies and products.

## Pilot Studies – In Search of Innovative Remedial and Restoration Design

### MP076 A Case Study on Adaptive Management and the Optimization of a Pilot Bank Stabilization Remedy for a Mercury-Impacted River

*J. Collins, C. Dixon, AECOM; N.R. Grosso, M. Liberati, E. I. du Pont de Nemours and Company*

Historical mercury (Hg) releases occurred at a textile manufacturing facility on the South River, Virginia. These releases resulted in increased Hg concentrations in biotic and abiotic media, which have not declined over the past thirty years, as originally expected. Introduction of legacy Hg impacted soils to the South River through bank erosion is the highest source of Hg loading to the system. In 2009, a bank stabilization pilot (Bank Pilot) was constructed along a 500-ft reach of the South River to test this hypothesis and to assess whether control of Hg loading to the water column and sediment through eroding banks would result in reductions of Hg concentrations in the aquatic environment. Post-implementation monitoring data documented significant mercury concentration reductions in near-bank sediment and pore water samples within three to five years, which demonstrated the effectiveness of the remedial approach. An analysis of remedial alternatives identified bank stabilization techniques similar to those used at the Bank Pilot as the most viable, implementable, cost effective and sustainable remedial option to address Hg loading to the river from eroding riverbanks. Due to the size, linear nature, complexity and spatial variability of the South River system, achieving remedial action objectives identified for the program are best achieved in an adaptive management framework. This approach began with implementation of a series of Interim Measures (IM) at select bank management areas (BMAs) within the first two river miles downstream of the former site. The first IM was completed at the Constitution Park BMA and incorporated learnings from the Bank Pilot project, as well as modifications intended to address landowner preferences, including the preservation of mature riparian habitats. Three IMs have been designed and implemented on the South River to date, with two additional projects currently under design. This presentation will discuss the adaptive management process being used to effectively scale and improve upon an initial pilot study to address mercury loading to the South River from eroding riverbanks.

### MP077 Advances in the Role of Phytotechnologies in Sustainable Site Remediation and Reclamation

*B. Zeeb, Royal Military College / Chemistry Chemical Engineering Dept; K. Yun, L. Morris, Royal Military College of Canada; A. Litalien, Royal Military College of Canada / Chemistry and Chemical Engineering; R. Bergin, E. Mann, A. Rutter, Queens University / School of Environmental Studies*

It is becoming increasingly important to develop more sustainable remediation technologies to clean up the literally 1000's of contaminated Brownfield sites within our communities. These are lands that were previously used for industrial or commercial purposes, and have the potential to be reused once they are cleaned up. The traditional remediation strategies for dealing with many types of contaminated soils involve excavation of the soil followed by transport to an off-site treatment facility or to a hazardous waste disposal site. These methods, although expedient, are typically energy-intensive and costly. Furthermore they may affect the environment in other adverse ways through spills during transport, and they disrupt the local ecosystem by removing or destroying the native soil. Increasingly, contaminated site owners, government legislators, and environmental consultants are turning to more 'green' technologies which additionally create new green spaces and decrease $CO_2$ emissions. Phytotechnologies are clearly 'green' technologies, driven by solar energy. In most cases the contaminated soil is remediated in place and is then re-usable. By developing these technologies, we are not simply transferring the liability for contaminated matter from one area (the contaminated site) to another (a landfill). Vegetating the land also acts in our favour in terms of greenhouse gas storage which has been estimated at ~6 tonnes per hectare. Finally, phytotechnolgies can be very cost effective and costs may be spread out over several years. The technology is however very site-specific and it can take years to fully remediate a site using phytotechnologies alone. In many cases, there may be a role they play alongside our more traditional remediation technologies. In every instance, we need to take into account factors including the contaminant type and concentration, the soil make-up, the hydrology of the site, the climate, the native plants at the site, etc. This presentation will highlight examples of phytotechnologies involving metal, organochlorine, petroleum hydrocarbon, and salt-contaminated sites, and will emphasize the integration of plant-based remediation technologies into our portfolio of remediation strategies

### MP078 Concept Maturation of a Coastal Restoration Program Following Successful Implementation of a Pilot Project

*C. Hauser, AECOM; J. Mattei, Sacred Heart University; C. Mancini, AECOM / Environment Health; M.R. Liberati, E.I. DuPont de Nemours and Company / Corp Remediation*

Stratford Point is located at the mouth of the Housatonic River Estuary in Fairfield County, Connecticut. A trap and skeet range was operated at the site from 1926 to 1986 resulting in the discharge of lead shot into surrounding water and sediment. From 2000 to 2011, accumulated lead shot in upland, intertidal, and subtidal areas was removed via excavation. After the excavation, erosion of intertidal sediment exposed residual lead shot at the sediment surface, providing a potential ingestion hazard to foraging waterfowl. In 2014 a 150-foot living shoreline pilot project was constructed as a "proof-of-concept" to demonstrate the potential for living shorelines to decrease erosion of intertidal sediments, reduce potential ecological exposure to contaminants, and restore wildlife habitat. Post-construction monitoring demonstrated that the pilot project effectively promoted sediment accretion, which provided a natural cap over the residual lead shot. Based on these positive results, the pilot project was expanded in November 2016 to protect and enhance an additional 750 linear feet of shoreline. On-going monitoring has demonstrated that, although the living shoreline effectively reduces erosion of intertidal sediments, it is less effective at reducing erosion of the coastal dunes located above mean high water (MHW), which may cause additional lead shot to be revealed. To address this concern, the living shoreline restoration was modified to include additional design elements. In November 2017, oyster cultch (shell) was used to construct a sill, behind which imported sand and soil were placed. Large woody debris was anchored into the sand and soil, which were then planted with *Spartina patens* and *S. alterniflora*. These elements were intended to form a natural, porous medium of shell that would absorb hydraulic energy, promote wave run-up, and generate beneficial vortices, thus reducing wave energy and causing mounds of non-uniform deposition of sand and gravel. Preliminary post-construction monitoring results have been positive. The maturation and evolution of this pilot project concept through construction demonstrates the value of using adaptive management strategies to implement flexible, proactive restoration increasing the likelihood of a successful outcome.

**MP079 Optimizing the sorption of phenol on rice husk powder by immobilised microbial cells**

*A.A. Oguejiofor, University of Nigeria, Nsukka / Biochemistry; C.O. Onwosi, University of Nigeria / Department of Microbiology; I.N. Onwurah, University of Nigeria / Biochemistry*

Phenols, dyes and heavy metals, are amongst the most important environmental pollutants being faced today. They are typically present in wastewater from industrial processes, such as the petrochemical and pharmaceutical, paper and pulp industries. They contaminate the soil, groundwater, sediments and surface water and their removal from wastewater before discharge into the environment is important. Thus, more efficient and rapid methods of removal and detoxification are urgently needed. This study was aimed at optimizing the efficiency of rice husk as a biosorbent for the removal of phenols and their congeners from liquid wastes and to evaluate their possible application in activated sludge process. In doing so, the elemental and physicochemical compositions of rice husk powder (RHP) to be used as biosorbent were evaluated while microorganisms to be immobilized were isolated from the industrial effluents and thereafter characterized. The selected the microorganism was immobilized on the rice husk powder. The rates of adsorption of phenol on the rice husk powder at different phenol concentrations, biosorbent dose (biomass), pH, temperature, and contact time were determined using Fourier Transform Infrared Spectrophotometer (FTIR). The rate of adsorption of phenol on rice husk powder without immobilized cells was also determined. The adsorption kinetics, equation which best describes the equilibrium uptake and the isotherms which best describes the data obtained were evaluated and the thermodynamic parameters (?G$^o$, ?H$^o$ and ?S$^o$) determined. The elemental analysis of the rice husk powder (RHP) showed the presence of Iron (ppm) 20.396, Aluminum (ppm) 5.478, and Nitrogen 0.923 while the FTIR–spectra of RHP showed the participation of phenols (O-H), amine (N-H), alkyne (C≡C), carbonyl (C=O), aromatic amine (C-N). The biosorption process followed the pseudo first order reaction order with ?G estimated to be -3.772KJ/mol., suggesting that the removal process could be exothermic and spontaneous. More so, the immobilized *Bacillus cereus*on rice husk powder resulted in enhanced removal of phenol and their congeners when compared with the rice husk powder without immobilized cells. This implies that Rice Husk Biomass having immobilized *Bacillus* spp. can be used in activated sludge process for removal of phenols from industrial wastewater.

**MP080 Phytoextraction: A Sustainable Solution to Soils Contaminated with Cement Kiln Dust Leachate**

*A. Litalien, B. Zeeb, Royal Military College / Chemistry and Chemical Engineering Dept*

Cement is a ubiquitous building material with global production approaching 3.3 billion metric tonnes annually. A by-product of cement manufacturing, known as Cement Kiln Dust (CKD) poses significant environmental risk as it is highly alkaline and enriched in salts. Despite this, CKD has been historically disposed of by on-site landfilling and as a result, cement manufacturing plants often have severely salinized soils. Soil salinization decreases both soil quality and vegetative cover, thus negatively impacting local ecosystems. This case study examines the use of plant-based technologies for the remediation of a marshland adjacent to a CKD landfill site at the Lafarge-Holcim plant in Bath, Ontario, Canada. Salt-tolerant plants known as halophytes have been used to stabilize and extract salts from contaminated soil and groundwater, a process known as phytoextraction. Plant species were selected based on their salt tolerance mechanisms: accumulation of salts in above-ground plant tissue, and the secretion of salts on leaf surfaces. While accumulator plants may incorporate large amounts of salts into their tissues throughout a growing season, this biomass requires harvesting and disposal in order to eliminate it from the site. Salts that are excreted however, may be dispersed by wind action allowing for continuous extraction of salts and requiring less maintenance. This study integrates both salt tolerance mechanisms with the aim of optimizing soil chloride extraction and lowering management costs. The ongoing study at the Bath cement manufacturing plant is the first of its kind to implement both accumulator and excretor halophytes for the remediation of salt-contaminated soils. This work will inform future remediation strategies both for the Bath site and for other CKD contaminated regions worldwide. With refined methods, phytoextraction can be a suitable technology for addressing soil salinization.

## Fate and Effects of Metals – Mechanisms of Bioavailability and Toxicity

**MP081 Do DOC characteristics matter? A case study investigating metal toxicity to a tropical freshwater alga**

*G. Macoustra, University of Wollongong / SMAH; A. Holland, La Trobe University; J. Stauber, CSIRO Land and Water; D.F. Jolley, University of Wollongong / School of Chemistry*

Dissolved organic carbon (DOC), common to natural waters, plays a key role in influencing metal speciation and bioavailability. The ability of DOC to alter the toxicity of metals depends on its concentration, source and composition. Each aquatic system is distinct, with a unique combination of organic matter sources, resulting in DOC with complex and heterogeneous chemical compositions. Currently, there is limited research comparing the ameliorative effects of different Australian DOCs on metal toxicity. This information is required if we are to improve bioavailability-based models for derivation and application of water quality criteria for metals. This study involved determining the effect of three distinct Australian DOCs on the toxicity of copper and nickel to a tropical green alga *Chlorella* sp 12. Inhibition of cell division over 72 h, at a range of copper (0-100 µg Cu/L) and nickel (0-2000 µg Ni/L) concentrations was investigated in the presence of each of the DOCs (0, 2 and 10 mg C/L added). Both dissolved and bioavailable metal (using diffusive-gradients in thin-films, DGT) were determined over 72 h. Copper toxicity was reduced in the presence of all DOCs, with up to a 4-fold increase in EC values with increasing DOC concentration, and up to a 2-fold difference in toxicity between the different DOC types. In contrast, DOC concentration or composition had little effect on Ni toxicity to this alga. The amelioration of copper toxicity of the three DOCs varied between wet and dry seasons. Changes in protective ability of the DOCs were significantly related to the aromaticity of the DOCs, with EC values increasing with increasing aromaticity. Potentially bioavailable, or DGT-labile, metal concentrations varied between different DOC treatments. There was good agreement between DGT-labile copper concentrations and the predicted ameliorative effect of the DOC based on its chemical characteristics. DGT-labile copper was highest in the least protective DOC treatment and lowest for the most protective DOC, with up to a 2-fold difference in DGT-labile copper. These results demonstrate that metal bioavailability and toxicity vary with both the source, concentration and composition of DOCs in freshwaters. Thus, the development of protective water quality criteria for metals requires a greater understanding of DOC composition, how composition influences DOC-metal interactions and to what degree these components vary between metals, regions and seasons.

**MP082 The Influence of Major Freshwater Ions on the Toxicity and Kinetics of Silver Nanoparticles in Toxicological Media**

*C. Walli, Western Washington University / Huxley College of the Environment; R.M. Sofield, Western Washington University / Department of Environmental Sciences*

Silver nanoparticles (AgNPs) are increasing in presence in commercial and medical products due to their bactericidal properties. Aqueous silver ($Ag^+$) toxicity to freshwater organisms has been well studied using the Biotic Ligand Model (BLM). There is strong evidence to suggest $Ag^+$ as the toxic mechanism of action of AgNPs, however toxicity via ionic dissolution from AgNPs is not accurately predicted by the BLM, which suggests the existence of other or additional chemical or biological reactions. Furthermore, consensus on the toxicity of AgNPs has not yet been achieved due the variety of behaviors that AgNPs exhibit depending on their physical properties, such as size or capping agent, or surrounding environmental conditions, such as pH or temperature. As a result, there has been a call to standardize toxicity tests for nanomaterials differently than what is used for other chemicals. The purpose of this research is to observe the effects of the major freshwater ions $Ca^{2+}$, $Na^+$, $Cl^-$, and $SO_4^{2-}$ on the toxicity of AgNPs to *Daphnia magna*. This study uses 8 acute toxicity tests performed in ASTM moderately hard synthetic freshwater that have varying additions of each ion. The BLM predicts that all experimental synthetic freshwaters will reduce $Ag^+$ toxicity in comparison to ASTM moderately hard water without any additions, driven by the concentration of total ions in solution. Nanoparticle kinetic theory also predicts a reduction of dissolved $Ag^+$ concentration caused by a combination of major ion concentration and valency, theoretically reducing $Ag^+$ toxicity from AgNPs. Completed toxicity tests in this study have shown that both of these mechanisms influence toxicity with increases of LC50s much higher than what the BLM predicts for each experimental synthetic freshwater. Factorial analysis is used to determine the specific influence of each freshwater ion on differences in toxicity as well as the measured chemical behaviors: particle concentration and size distribution on ICP-MS, and sedimentation using UV-Vis spectrophotometry. This research aims to examine whether predicted AgNP kinetic behavior occurs in toxicological media and connect how specific particle behaviors influence toxicity in a standardized test. These results could inform nanomaterial-adapted test standards, and also understand the impact of specific major ions in freshwater ecosystems on the environmental toxicity of AgNPs.

**MP083 Toxicity to *Ceriodaphnia dubia* in natural waters with extreme levels of hardness and dissolved organic carbon**

*C.D. Ivey, J.M. Besser, D. Cleveland, J.A. Steevens, USGS / Columbia Environmental Research Center; C.E. Schlekat, NiPERA; E.J. Van Genderen, International Zinc Association, Environment & Sustainability*

Most US states use outdated hardness-based criteria to regulate most metals in surface waters. Slow adoption of new criteria based on biotic ligand models (BLMs) reflects uncertainty about whether these models can reliably predict metal toxicity to aquatic biota across wide ranges of water quality conditions affecting bioavailability. BLMs reflect the influence of multiple water quality variables that influence bioavailability, including pH, hardness [calcium and magnesium], and dissolved organic carbon (DOC). BLMs were developed and validated based on tests with wide ranges of water quality conditions, but model validation with natural waters containing extreme values of one or more water quality parameters is still needed. We generated toxicity data (*Ceriodaphnia dubia*) for natural waters representing extremes of water quality in the Midwestern US. We sampled two in each of two study areas: (1) central Illinois, where streams had high hardness (>300 mg/L) and moderately low DOC (2-4 mg/L); and (2) northern Minnesota, where streams had high DOC (>30 g/L) and low hardness (17-27 mg/L). We conducted chronic toxicity tests with waters from two sites in each study area, plus two low-DOC (< 1 mg/L) laboratory waters with hardness adjusted to match each natural water. *C. dubia* tests showed somewhat different trends between the two metals. Nickel EC20s (for reproduction) varied widely (11-fold difference) across the six waters tested, and showed a clear trend for reduced toxicity at higher DOC concentrations. Nickel EC20s were 8.8-12.0 ug/L in the low-DOC lab waters and 66-98 ug/L in the high-DOC Minnesota waters. No protective effect of hardness on nickel EC20s was evident, perhaps because of the prevailing effect of DOC in the soft Minnesota waters. Zinc EC20s showed less overall variation among test waters (5.3-fold) and showed no clear trend for protective effect of either hardness or DOC. Effects of water quality differences on zinc toxicity may have been obscured by the wide confidence intervals for most zinc EC20 values. This uncertainty reflects changes in measured filterable zinc concentrations in exposure chambers during each 24-hour water replacement cycle, which made it difficult to determine which zinc analyses best reflect test organism exposure. Observed differences in toxicity of zinc and nickel will be compared to BLM predictions.

**MP084 Investigation of the Toxicity of Different Metal Species Using an in vitro Approach**

*D. Oldham, Oklahoma State University; M. Minghetti, M. Ibrahim, Oklahoma State University / Integrative Biology*

In solution, metals form different chemical species based on water chemistry and medium composition. It is generally accepted that free metal ions, and, with less efficiency, neutral complexes are the main drivers of toxicity in fish due to their ability to cross the cell membrane. However, recent studies have brought this hypothesis into question. In order to evaluate the bioavailability of neutral and charged metal complexes, as well as free metal ions, exposure media will be designed to allow the formation of a variety of metal species in solution. The rainbow trout (*Oncorhynchus mykiss*) gut cell line (RTgutGC) will be used to investigate the bioavailability of the different metal species. Metal speciation analysis, performed using the chemical equilibrium model Visual Minteq, showed a wide range of chemical species forming among the four metals tested in this study (silver, cadmium, copper and zinc). Following exposure, toxicity, bioaccumulation and bio-reactivity of free ionic, neutral or charged metal species will be measured in RTgutGC. Toxicity will be determined by a multiple endpoint assay measuring simultaneously cell metabolic activity, cell membrane and lysosomal integrity, bioaccumulation by ICP-MS and bio-reactivity by measurement of metallothionein mRNA levels. The metals had distinct affinities to certain anions, for instance: copper showed strong affinity for phosphates and carbonate, and removal of carbonate allowed hydroxyl species to form. Silver and Cadmium showed a high affinity for chloride and zinc remained principally in free ionic state. Preliminary results in cells exposed to Cadmium have shown differing effects among different media. With low chloride media, and phosphorous free media containing carbonate, Cadmium was significantly more toxic in regards to metabolic activity than in the control high chloride synthetic media. Applying both the Visual Minteq results with the toxicity, bioaccumulation and bio-reactivity results will allow a better understanding of which metal species plays the largest role in toxicity, and transport across the membrane. This information could be used to improve bioavailability models such as the biotic ligand model.

**MP085 Toxicity and Bioavailability of Cobalt: Validation of a Cobalt Biotic-Ligand Model**

*A.S. Cardwell, Oregon State University / Department of Environmental and Molecular Toxicology; R.C. Santore, Windward Environmental, LLC; P. Marsh, Cobalt Institute; B.A. Stubblefield, Oregon State University / Environmental and Molecular Toxicology*

It is well known that the bioavailability and toxicity of metals, including cobalt (Co), vary based upon water quality characteristics (e.g., hardness, pH, dissolved organic carbon [DOC]) of freshwaters. In order to account for the changes in the bioavailability of Co to aquatic organisms, extensive toxicity testing has occurred for the development of a Co-specific chronic biotic ligand model (BLM). This model was developed based upon toxicity tests using three aquatic organisms: the fathead minnow, *Pimephales promelas*, the cladoceran, *Ceriodaphnia dubia*, and the green algae, *Pseudokirchneriella subcapitata*, with exposure to

Co concentrations across a range of water quality characteristics (e.g., calcium, magnesium, sodium, pH, DOC). Following development of the Co BLM, a two-phase validation was conducted. A combination of tests in reconstituted laboratory waters and field-collected natural waters were conducted with organisms not used in the BLM development as a model validation exercise. Chronic toxicity tests were conducted using three species: the aquatic plant (*Lemna minor*), a gastropod (*Lymnaea stagnalis*), and a rotifer (*Brachionus calyciflorus*). Two Co-BLM parameter models (one for plants/algae and one for fish/invertebrates) were used to provide model predictions versus observed effects. Observed effects, calculated as 10% effect concentrations ($EC_{10}$s) and 95% confidence intervals around the toxicity values, were considered in evaluating observed versus model predictions. In validation testing of *B. calyciflorus* in laboratory waters, the BLM predicted effects in 8 of 10 tests within a factor of two. In testing with field-collected waters, the model predicted the majority of effect concentrations for *L. minor* (5 of 5 natural waters), *L. stagnalis* (5 of 5 natural waters), and *B. calyciflorus* (4 of 5 natural waters), within a factor of 2. The results demonstrated that the BLM accurately predicts Co toxicity in field-collected natural waters and for organisms not used in the development of the bioavailability model.

**MP086 Role of chloride as a complexing agent in the exposure media on accumulation and bio-reactivity of silver and copper in bluegill fish**

*M. Ibrahim, E. Bates, M. Minghetti, Oklahoma State University / Integrative Biology*

In general, it is known that fish are less sensitive to metal toxicity in seawater than freshwater due to the higher concentration of salts that make the ionic forms of metals less available to bind with the uptake sites (e.g. the gill and the gut). However, some studies have shown metal toxicity in fish even at high salinity where metals mostly stay in complexed forms. Therefore, it is important to study whether metal complexes can become bioavailable and elicit toxicity. To investigate the accumulation and bio-reactivity of silver and copper complexes in bluegill fish, in this study, we first modelled different exposure solutions varying chloride concentrations (0-200 mM). Visual MINTEQ, a chemical equilibrium model, was used to determine the media composition that allows metal to speciate in different forms (i.e. ionic, neutral complex, and charged complex). Ag speciation was mostly dominated by the ionic form ($Ag^+$) at low chloride concentration (below 0.5 mM). With the increase of chloride, it was dominated by neutral ($AgCl_{(aq)}$) and negatively charged ($AgCl_2^-$) complexes. However, Cu speciation remained constant as $Cu^{2+}$, $Cu(OH)^+$, and $Cu(CO_3)^+$ up to 10 mM chloride concentrations, and after that it was $Cu(CO_3)^+$ that dominated the Cu speciation. Based on these speciation, we selected 0.05, 10, 50, 100, and 200 mM chloride containing solutions for bluegill salinity tolerance experiment. Fish were exposed to different solutions for 96 hours. In the 96-hour salinity exposure experiment, 100% fish mortality were observed at 200 mM solutions (~14.3 PPT). Variable proportions of mortality were found at other concentrations. From this preliminary experiment, we have now chosen three solutions (0.05, 3, and 50 mM chloride) to evaluate accumulation and bio-reactivity (i.e. induction of metallothionein mRNA levels) of different Ag and Cu metal species in bluegill fish (*Lepomis macrochirus*). Fish will be exposed to a sub-toxic concentration of each metal for 96 hours. After exposure, gill, liver, gut, kidney and blood will be collected to measure metal accumulation using ICP-OES and bio-reactivity using qPCR techniques. This study will shed light on the bioavailability of metal complexes in fish.

**MP087 Dynamic variation of metal bioavailability related with responsive mechanisms of molecular biomarkers using in-situ exposure**

*Z. Wang, Jiangxi University of Science and Technology*

Due to the complexity of heterogeneous sediment, the chemical speciation and mobility of metals were in dynamic conditions rather than steady states, resulting in high variability of contaminant bioavailability. Chemical analyses in traditional tests had disadvantages of inaccuracy for contamination characteristics and risk assessments, representing a worst-case scenario in terms of complex exposure dynamics. In this presentation, relevant scientific issues regarding the effects on subcellular distribution and molecular biomarkers with special emphasis on toxic mechanisms and their associations were investigated through powerful experimental designs and field-based manipulations of in situ exposure and kinetic DGT approach. Understanding the degree of pollution and geochemical characteristics of sediment matrix, in situ testing chambers were deployed combining the DGT and caged clam *Ruditapes philippinarum*, and the dynamic exchanges, translocation and mobilization were then clarified among the interface of particles and pore-water in sediments through measuring dynamic parameters and resultant induced fluxes in exposed organism. Integrating a wide battery of biomarkers, dynamic changing processes were assessed, and their interactions were established between exposure and biological effects. Furthermore, variations of transcript expression of functional genes in contaminant-specific biomarkers were obtained through high throughput oligo-DNA Microarray and quantitative reverse transcription polymerase chain reaction in order to elucidate the mechanistic understanding of molecular biomarkers in biological responses. Simultaneously, the approach of in-situ evaluation was established considering the consistency of framework as protocols among sediment chemistry, contaminant bioavailability and adverse effect, which significantly improve accuracy and ecological relevancy in complex exposure situation and thus provide a robust tool to support more comprehensive processes of sediment risk assessment. Overall, the associations not only revealed the fates of accumulated metals, but scientifically favored an improved understanding of exposure and toxic effects in response to subcellular level, supporting the focus of metabolic availability assessment on the intracellular processes or events occurring within organism in future metal biomonitoring. (The author acknowledges financial support by Grant No. 21377125/B070403 from National Nature Science Foundation of China).

**MP088 Transcriptome analysis revealed the effects of different metals levels exerted on *Crassostrea hongkongensis* chronically exposed in wild**

*Y. LI, Hong Kong University of Science and Technology / Division of Life Science; W. Wang, Hong Kong University Sci. Technol. / Department of Ocean Science*

Oysters *Crassostrea hongkongensis* can hyper-accumulate trace metals and survive under high levels of contaminants. We sampled *C. hongkongensis* and identified the transcripts sequences acquired from transcriptome analysis of their gill tissues, coupling with the determinations of metals (Ag, Cd, Cr, Cu, Ni, Pb, Zn). During the long-term chronic exposure, the oysters became blue colors. Our results demonstrated the increase of Zn and Cu transporter expression in oyster soft tissues with the high bioaccumulation of these metals. More than 100,000 genes were assembled *de novo*, and totally 1944 DEGs were identified in the contaminated oysters. Increased expression of genes related to energy production was observed in two contaminated sites, and was significant at the medium contaminated levels. We found severe disruption of cytoskeleton in most contaminated sites. The possible roles of histone modification were also identified in response to metal stress. This study illustrated the molecular mechanisms of metals toxicity in oysters chronically exposed in the filed.

**MP089 Alterations in Some Biochemical Parameters of *Clarias gariepinus* following Subchronic Exposure to Magnesium Hydroxide Nanoparticles**

*A. Bukola, O.I. Omotade, O. Olalekan, Ekiti State University, Ado Ekiti / Department of Biochemistry; A.E. Temitope, Federal University of Technology, Owerri / Department of Fisheries and Aquaculture Technology; A.A. Adekoke, Ekiti State University, Ado Ekiti / Department of Zoology and Environmental Science*

The aquatic environment is vulnerable to contamination from engineered nanomaterials. Magnesium nanoparticles (MgOHNPs) have gained commercial interest in the areas of waste remediation and recycling of waste water for portable use. MgOHNPs are among the least investigated nanoparticles and thus their toxicological effects are yet to be unveiled. The nanoparticle was characterized by UV/Vis spectrophotometry, fourier transform infrared spectroscopy (FTIR) and transmission electron microscopy (TEM). *Clarias gariepinus* were exposed to 62.5, 125 and 250 mg/L suspensions of small size (10 nm) MgOHNPs for 21 days under semi-static conditions. Thereafter, they were sacrificed and alterations in the haematological parameters and some biochemical indices in the plasma were examined. The water quality parameters such as chloride ions and dissolved oxygen significantly decreased, while pH, total alkalinity, carbon (IV) oxide, total hardness and nitrate increased significantly in the exposed media compared to the control medium. The results of this investigation revealed a concentration dependent increase in the plasma levels of albumin, total protein, magnesium, calcium, chloride, alkaline phosphatase and acid phosphatase. Whereas, the levels of aspartate aminotransferase, alanine aminotransferase, glucose, total bilirubin, potassium and creatinine decreased significantly. The haematological parameters remained unaltered in the fish at the tested doses. The results indicated that exposure to MgOHNPs could lead to disturbances in blood biochemistry of *Clarias gariepinus*. Key words: Subchronic, Exposure, Nanoparticles, Magnesium hydroxide, *Clarias gariepinus*.

**MP090 Investigating nickel uptake, tissue distribution and depuration in the green shore crab *Carcinus maenas***

*A. Cremazy, University of British Columbia / Department of Zoology; L. Nogueira, CAPES – Brazil; C.M. Wood, University of British Columbia / Zoology*

Nickel has been shown to accumulate and exert toxicity to estuarine and marine organisms, but Ni fate and effects in these organisms remain understudied compared to freshwater species. The green shore crab (*Carcinus maenas*) is a widely distributed euryhaline crustacean that is considered a model species for estuarine and marine ecotoxicology studies. Notably, this species has been extensively used to determine impacts of metal contaminants, because of the high capacity of their carapace to retain metals from the ambient water. The main goal of the present study was to provide insights into Ni uptake pathways and depuration strategies in this species. To this end, we characterized the uptake, tissue distribution and depuration of waterborne Ni ingreen crabs exposed for 24 h to 8.2 µg/L of radiolabelled Ni (the USEPA chronic saltwater guideline value). Various exposure conditions were tested to decipher uptake pathways (gills vs. carapace), depuration kinetics, as well as the geochemical vs. metabolic controls on Ni accumulation, including exposures at different temperatures, and carapace shielding experiments. Comparisons with Zn and Ca uptake and depuration dynamics were also made. (IDRC, NSERC Discovery).

**MP091 Uptake and loss kinetics of uranium in an aquatic insect**

*B. Henry, USGS / Biology; M.N. Croteau, USGS; D.J. Cain, USGS / Water Resources Division; D. Walters, J. Miller, USGS / Fort Collins Science Center*

Aquatic insects are the most abundant and diverse macroinvertebrate fauna of freshwater ecosystems. They also play a key role in linking aquatic and terrestrial ecosystems through their metamorphosis and dispersal to riparian habitats from aquatic larvae to winged adults. Adult insects are a vector for the transfer of chemical contaminants to terrestrial consumers, although this varies with the specific chemical. In the case of U, little of the larval body burden is carried by the adult, implying that the risk of U exposure is largely confined to the aquatic ecosystem. However, little is known about the underlying mechanisms governing U bioaccumulation kinetics by insect larvae. We used the precepts of a kinetic bioaccumulation model and experimentally parameterized U uptake and elimination rate constants in a model aquatic insect species, the mayfly *Neocloeon triangulifer*. The model can predict U accumulation and identify potential risk to consumers in impacted ecosystems. Experimental results showed that mayflies efficiently accumulate U from the aqueous phase, but only marginally from diet. Increasing concentrations of U in diet lowered mayfly feeding rates by more than 80%. Nearly 90% of the accumulated U was eliminated within 24 hours. A subsequent U desorption experiment indicated that 60% of the U accumulated after a pulse exposure to waterborne U desorbed within a minute of rinse. In contrast, similar extraction experiments conducted with the stonefly *Zapada* and the Ephemerellid mayfly *Drunella* showed no indication of desorption, suggesting that U was more strongly bound by these two taxa than by *N. triangulifer*. Our results highlight the importance of characterizing species specific processes and avoiding generalization of biokinetic processes to other taxa.

**MP092 Copper Uptake in Periphyton under Natural Stream and Wastewater Effluent Exposures**

*T. Vadas, University of Connecticut / Civil and Environmental Engineering; K. Turpin-Nagel, N. Fuad, University of Connecticut / Department of Civil and Environmental Engineering*

The bioavailability of copper to aquatic organisms is largely dependent on water quality characteristics, which can influence the chemical speciation. In natural waters, a large percentage of copper is found complexed with inorganic and organic ligands leaving a small percentage available as free metal ions. Complexation with dissolved organic matter (DOM) is fundamental in controlling metal speciation and the source of DOM has been shown to influence the binding strength of the ligands. Wastewater treatment plant (WWTP) effluent DOM has been observed to contain high-affinity binding sites for copper and higher percentages of hydrophilic binding ligands leading to enhanced copper complexation. Thus, metal speciation differences are expected to vary between aquatic environments impacted by urban discharges and those more pristine. The aim of the present study was to examine the uptake kinetics of copper to periphyton, a biofilm community of heterotrophic and autotrophic species that grow in running water ecosystems, under freshwater and WWTP effluent exposure conditions. Periphyton were colonized in indoor growth aquariums supplied with freshwater from the Fenton River (Connecticut, U.S.A). Copper uptake kinetic experiments were run using a constructed trickle apparatus, where short-term (90 – 380 minutes) exposures were completed using environmentally relevant total copper concentrations (2 – 16 mg/L) at varying levels of % WWTP effluent. First-order rate kinetics were used to analyze the differences in initial uptake rates between the different exposure waters over the first 30 – 60 minutes of exposure. It was found that as the percentage of WWTP effluent increases in the exposure waters that the periphtyon total and intracellular uptake rates decrease. Reduced periphyton copper content (surface bound and intracellular) was also observed for the exposure waters containing WWTP effluent. Free copper ion concentrations were estimated for the exposure waters by inputting measured water quality parameters and experimentally derived DOM conditional binding constants into Visual MINTEQ. An equilibrium ion exchange technique was used to investigate the exchangeable copper fractions of the exposure waters. Kinetics modeling using the total, free ion, and exchangeable copper concentrations allowed for examination of the bioavailable copper fraction. Measured uptake rates correlated well with those modeled based on exchangeable copper.

**MP093 Effects of Organism Age on *C. dubia* Acute Sensitivity to Zinc in Lab Water**

*S. Vasquez, B.C. Jorgenson, A.M. Briden, N. Lynch, Pacific EcoRisk*

The USEPA acute toxicity testing manual (EPA-821-R-02-012) requires that *Ceriodaphnia dubia* be less than 24 hours old at test initiation. Water effect ratio (WER) testing in accordance with the USEPA "Interim Guidance on Determination and Use of Water-Effect Ratios for Metals" (EPA-823-B-94-001) is performed following the test conditions outlined in EPA-821-R-02-012, including the requirement of < 24-hour old *C. dubia*. An assessment of zinc $EC_{50}$ values for 48-hour acute *C. dubia* lab water tests performed by Pacific EcoRisk (PER) showed substantial variability in lab control water $EC_{50}$ effect thresholds, with some values outside a factor of 1.5 of the mean of the PER database (hardness-normalized to 50 mg/L). Following this observation, a study was designed to see if this variability could be reduced in order to achieve more consistent and predictable $EC_{50}$ values for zinc in lab water. Organism age was investigated as a source of this variability; to investigate this potential source, tests were initiated with organisms of blocked age. Younger aged organisms showed improved test performance, with lower overall intratest and intertest variability. Results of zinc in lab control water are also compared with copper.

**MP094 Fish otoliths as tracers and records of inorganic contamination exposure – testing the key assumption**

*J. Brandt, USGS / Nicholas School of the Environment; M.R. Ross, Colorado State University; E.S. Bernhardt, Duke University / Biology; R.T. Di Giulio, Duke University / Nicholas School of the Environment*

Otoliths are acellular, carbonate structures located in the inner-ear cavity of teleost fishes. While their primary functions include balance, motion sensing, and hearing, their metabolic stability and approximately daily accretion rate also allow them to “record” certain aspects of a fish’s life-history. Historically, this characteristic has been exploited by population biologists and those studying the movement of migratory fish in and out of freshwater environments. More recently, ecotoxicologists have also incorporated otolith analyses into their assessments of polluted sites. Much of the work in this area has rested on the key assumption that inorganic water chemistry dictates that of otoliths and we tested this assumption with two independent projects. In the first, we showed that the $^{87}Sr/^{86}Sr$ isotope ratio of surface waters from a reservoir receiving coal combustion residual (CCR) effluents (~0.71013) was similar to that determined for largemouth bass otoliths collected from the same reservoir (~0.70996) and both ratios were statistically higher than those in corresponding samples from a nearby reference lake (all $p < 0.0001$). In the second, we compare time series otolith concentrations of five CCRs to overlapping time series of CCR loading from the associated coal-fired power plant. Here, we tested whether dramatic changes in water chemistry (e.g., a decrease in selenium (Se) loading from max rate of 2664 g/day to 124 g/day) were reflected by otolith chemistry. We observed substantial time lags between the two phenomena, differences within a given species, and differences among three species with distinct ecomorphologies, all of which challenge the assumption that inorganic water chemistry determines otolith chemistry for all elements. Together, our results indicate that (a) the shared Sr chemistry between water and otoliths from a CCR-receiving reservoir introduces otoliths as novel bio-tracers of contaminant sources, but that (b) otolith chemistry of some elements, like Se, additionally reflects dietary exposure. Ideas for an upcoming project to determine the relative contributions of water and dietary exposures to otolith chemistry—with the ultimate goal of developing a predictive model—will also be discussed. Drawing on fish physiology, exposure geochemistry, and hydrology, this work considers the biological fate of metals with potential applications and implications for aquatic contaminant monitoring going forward.

**MP095 Tissue Metal Concentrations in Atlantic Sharpnose Shark**

*R. Somerville, Jacksonville University / Marine Science; J. Gelsleichter, S. Ehnert, University of North Florida / Biology; G.K. Bielmyer-Fraser, Jacksonville University / Chemistry*

Metals occur naturally in the environment; however, anthropogenic practices have resulted in increased metal concentrations in sediments, waterways, and biota. Sharks are important species, both recreationally and commercially. Sharks occupy a high trophic level; and, tissue metal concentrations in these organisms may reflect metal transfer in aquatic food webs. Extensive research has been conducted on mercury toxicity in sharks; however, reference levels of other metals have not been established in many species. In this study, concentrations of nickel, copper, lead, cadmium, selenium, silver, zinc, and aluminum were measured in the muscle tissue of *Rhizoprionodon terraenovae* (Atlantic sharpnose shark),collected from Virginia to Texas. A total of 165 samples were analyzed for correlations among metals, size/age, gender, and location of capture. With the exception of mercury, there are no published data on tissue metal concentrations within this species along the eastern United States. This study provides reference levels of metal contaminants in the muscle tissue of Atlantic sharpnose sharks and provides insight into metal accumulation in this higher-level carnivore.

**MP096 Fate and distribution of cobalt in freshwater microcosms**

*M.C. Cavallaro, Oregon State University / Department of Environmental and Molecular Toxicology; E. Stefansson, Oregon State University; A.S. Cardwell, B.A. Stubblefield, Oregon State University / Environmental and Molecular Toxicology*

A series of aquatic microcosms were used to evaluate the fate and distribution of dissolved cobalt (Co) within a freshwater community. Nineteen 100-L microcosms were established with field-collected lake sediment and inoculated with laboratory and wild populations of algae, macrophytes, plankton, and benthic invertebrates. The study consisted of five nominal cobalt treatments: 0.5, 2.5, 12.6, 62.9, and 315.5 µg Co/L ($n$ = three microcosms per treatment) with four control microcosms. Water quality parameters and cobalt concentrations in water, pore water, sediment, and biota were measured throughout a 56-day exposure period. Rapid losses of cobalt from the water column were observed during the first 14 days of the study, and microcosms were re-spiked daily to maintain the target nominal concentrations. During this state of flux, rapid loss of Co in the water column was analytically confirmed as a result of biological uptake, presuming a state of equilibrium was ultimately reached. Water column Co concentrations were strongly correlated to biota Co tissue concentrations (correlation coefficient; $r = 0.88$), more so than sediment ($r = 0.44$) or pore water ($r = 0.38$) Co concentrations. High bioaccumulation of cobalt was found, particularly in the primary producers. At the termination of the test, mean measured (± SD) cobalt concentrations in highest treatment for *Lemna minor*, *Elodea canadensis, Myriophyllum pinnatum, a*nd mixed periphyton taxa were 4860 (± 1593), 4401 (± 459), 890 (± 25), and 1904 (± 309) µg/g dw Co, respectively. These results suggest that under these test conditions (i.e., closed, static system), primary producers display an enhanced ability to accumulate Co. Invertebrate community data indicate effects to cladoceran populations at exposures > 62.9 µg Co/L, with concomitant increase in phytoplankton likely due to decreased grazing pressure. Data generated from the present study improved our understanding of the fate and distribution of dissolved cobalt and highlight the potential indirect impacts chronic cobalt exposure may have on primary consumers.

**MP097 Use of benthic community structure and metal concentrations in biota to assess the effectiveness of mine reclamation activities**

*S. Collyard, Washington State Department of Ecology; J.M. Morris, Abt Associates; C. Larson, Washington State Department of Ecology*

Concentrations of metals in streams are typically assessed through the collection of surface water grab samples over short durations. This sampling approach may not reflect actual conditions, especially when inputs of metals are episodic or seasonal. Measuring changes in community structure associated with metals concentrations in benthic biota may represent a better way to assess management actions that prevent metal contaminated water from entering streams. In 2013, the Washington State Department of Ecology implemented a study in a metal contaminated stream impacted by historic copper mining activities, using the above approach to assess the effectiveness of mine remediation efforts. Initial results indicate that metals concentrations in sediment and surface water did not correlate well with remedial actions, concentrations of metals in periphyton, or changes in a measure of macroinvertebrate health. However, metals concentrations in periphyton did responded predictably to remedial actions meant to eliminate surface and subsurface discharges of metal contaminated water to the creek. Additionally, macroinvertebrate health, as indicated by an index of biological integrity, tracked well with metals concentrations in periphyton collected at the same locations. These results suggest biological communities have great potential for tracking remediation efforts at sites impacted by elevated inputs of metals.

**MP098 Trace Element Concentrations in Cetaceans Taken for Human Consumption off St. Vincent, West Indies**

*M. McCormack, Texas State University, San Marcos / Biology; R. Fielding, University of the South / Department of Earth and Environmental Systems; B. Jackson, Dartmouth College / Department of Earth Sciences; D. Bergfelt, Ross University / Department of Biomedical Sciences; J. Dutton, Texas State University / Department of Biology*

Cetaceans are long-lived top predators which can accumulate high concentrations of trace elements in their tissues. In St Vincent, several small cetacean species are taken for human consumption each year. This study investigated the concentration of As, Cd, Cr, Hg, Pb, and Se in 4 tissues (muscle, blubber, kidney, liver) from 5 species of cetaceans [false killer whale (*Pseudorca crassidens*), killer whale (*Orcinus orca*), Risso's dolphin (*Grampus griseus*), short-finned pilot whale (*Globicephala macrorhynchus*, and unidentified dolphins from the Stenella genus (*Stenella* spp.)] using microwave acid digestion and Inductively Coupled Plasma Mass Spectrometry (ICP-MS) analysis. There was a large intra- and interspecies variation in trace element concentrations. The highest mean concentration of Pb (1.22 µg/g dry wt), As (8.66 µg/g dry wt) and Cr (4.21 µg/g dry wt) were found in *G. macrorhynchus* liver, *P. crassidens* liver and *O. orca* muscle, respectively. Hg, Cd, and Se were found at highest concentration in the liver, followed by kidney and muscle, and lowest in the blubber in *P. crassidens*, *G. macrorhynchus* and *O. orca*. The mean liver Hg concentration in *O. orca* and *P. crassidens* was > 1,000 µg/g dry wt, and some individuals had a concentration that exceeded 3,000 µg/g dry wt. For all species, there was a strong correlation ($R^2 > 0.96$) between Hg and Se concentrations in the muscle, kidney, and liver. All muscle samples had a Se:Hg molar ratio < 1, whereas all blubber samples had a Se:Hg molar ratio > 1; this indicates that Se may have a protective role against Hg toxicity for blubber, but not for muscle. With the exception of *G. griseus*, all species had an average muscle, blubber, liver and kidney Hg concentration, and average muscle, liver, and kidney Cd concentration that exceeded the *Codex Alimentarius* Commission Food Standards Program (FAO and WHO) Hg and Cd recommendation of 1.0 µg/g wet wt and 0.1µg/g wet wt, respectively. Local government officials in St. Vincent should consider the concentration of trace elements, along with cultural practices and economic impacts when making recommendations regarding the consumption of cetaceans.

## Indoor Human Exposure to Particulate Matter and Persistent Toxic Chemicals: Emission Patterns, Fate and Health Risk

**MP099 Kinetics of Brominated Flame Retardant (BFR) Releases from Granules of Waste Plastics**

*B. Sun, Jinan University*

Plastic components of e-waste contain high levels of brominated flame retardants (BFRs), whose releases cause environmental and human health concerns. This study characterized the release kinetics of polybrominated diphenyl ethers (PBDEs) from millimeter-sized granules processed from the plastic exteriors of two scrap computer displays at environmentally relevant temperatures. The release rate of a substitute of PBDEs, 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE), from the waste plastics, was reported for the first time. Deca-BDE was the most abundant PBDE congeners in both materials (87−89%), while BTBPE was also present at relatively high contents. The release kinetics of BFRs could be modeled as one-dimensional diffusion, while the temperature dependence of diffusion coefficients was well described by the Arrhenius equation. The diffusion coefficients of BFRs (at 30 °C) in the plastic matrices were estimated to be in the range of $10^{-27.16}$ to $10^{-19.96}$ $m^2 \cdot s^{-1}$, with apparent activation energies between 88.4 and 154.2 $kJ \cdot mol^{-1}$. The half-lives of BFR releases (i.e., 50% depletion) from the plastic granules ranged from thousands to tens of billions of years at ambient temperatures. These findings suggest that BFRs are released very slowly from the matrices of waste plastics through molecular diffusion, while their emissions can be significantly enhanced with wear-and-tear and pulverization.

**MP100 Organic Flame Retardants in Egyptian Indoor and Outdoor Environments: Levels, Sources and Implications for Human Exposure**

*M. Serageldin, Douglas County Health Department / Air Quality; R. Lohmann, Graduate School of Oceanography, University of Rhode Island, Narragansett / Chemical Oceanography*

Little is known about the presence of the polybrominated diphenyl ethers (PBDEs), alternative flame-retardants (NFRs) and organophosphate flame retardants (OPFRs) in developing countries. This study investigated – for the first time – concentrations, sources and exposure levels of PBDEs, NFRs and OPFRs in the indoor and outdoor environments of Alexandria, Egypt, in dust and gas-phase samples. Passive samplers were deployed (n = 78) to determine gaseous concentrations, and various dust samples were collected from apartments (n = 25), working places (n = 14), cars (n = 18), and outdoors (OD, n = 30). Indoor gaseous (PBDEs: 7.0 – 300 pg/$m^3$; NFRs: 0.20 – 13 pg/$m^3$; OPFRs: 7.0 – 64 pg/$m^3$) and dust concentrations (4.0 – 770 ng/g; 0.50 – 8.5 ng/g; 150 – 1,850 ng/g) were significantly higher than outdoor (0.20 – 41 pg/$m^3$ and 0.50 – 475 ng/g) concentrations. BDE-47, 99, HBB, BTBPE and DDC-CO, tris-1,3-dichloropropyl phosphate (TDCPP), tris(1-chloro-2-propyl) phosphate (TCPP), tri (2-butoxyethyl) phosphate (TBEP) and triphenyl phosphate (TPP) dominated in all samples with more indoor variabilities. Profiles of PBDEs, NFRs and OPFRs in OD and floor dust were similar but differed from elevated fine dust, possibly due to the influence of carryover of OD by shoes. Although factors such as number of electronics, number of foamed furniture, construction year and floor type significantly correlated with the majority of PBDE congeners, chlorinated OPFRs and some NFRs in apartments and working places, sources were not clearly identified for NFRs. Significant log-linear relationships were observed between dust-air partitioning coefficients and octanol – air-partitioning coefficients in all microenvironments, indicating an equilibrium partitioning between dust and vapor. Exposure assessment indicated low possibility of occurrence of adverse health effects, with the inhalation pathway (for adults) and dust ingestion (for children) acting as the more important exposure routes.

**MP101 Phthalates, PAHs and Hopanes in Dust Collected in Homes Involved in the Canadian Healthy Infant Longitudinal Development Study**

*L. Jantunen, Environment and Climate Change Canada; S. Bernstein, G. Navaranjan, University of Toronto; J.M. Diamond, Tetra Tech, Inc.; S. Harris, Cancer Care Ontario & University of Toronto / Population Health and Prevention, Prevention and Cancer Control; T. Takaro, Faculty of Health Sciences / Simon Fraser Univ.; J. Scott, U Toronto; A. Beker, University of Manitoba; P. Mandhane, Univ AB; P. Subbarao, Sickkids Hospital; S. Turvey, University of British Columbia; D. Lefebvre, M. Sears, McMaster University; J. Brook, Environment and Climate Change Canada*

Exposure to semi-volatile organic compounds (SVOCs) including phthalates and polycyclic aromatic hydrocarbons (PAHs) may be associated with the development of childhood asthma. Phthalates have a wide range of consumer applications including plasticizers, fragrance "keepers", adhesives and sealants, paints and coatings, plastic and rubber materials and other products largely found in the indoor environment. PAHs are produced from incomplete combustion and have some petrogenic sources with dominantly indoor sources including cigarette smoke, emissions during cooking, and fireplaces. The Canadian Healthy Infant Longitudinal Development (CHILD) Study is a population-based birth cohort examining the origins of asthma and allergic disease. We present results characterizing phthalates, PAH and hopanes in dust collected from CHILD Study homes when the infants were 3-4 months of age. The concentration of phthalates and PAHs in dust is hypothesized to be a useful indicator of exposure for epidemiological analyses examining possible associations with the development of asthma and other related outcomes. Pregnant mothers were enrolled in the CHILD study between 2009-2012 from 4 cities and 1 rural area in Canada. Dust samples were collected from the floor of the most used room and bedroom by trained research assistants using a standardized protocol. Children underwent clinical assessments and were phenotyped at 1, 3 and 5 years. Archived dust samples were analyzed for 6 phthalates, 16 PAHs and 12 hopanes. Hopanes are present in engine lubricants and were included to estimate exposures related to traffic air pollution in the home. Preliminary results show that levels of these compounds differ among homes; in general, the concentrations of phthalates were greater than levels of PAHs which in turn were greater than levels of hopanes. House dust concentrations of SVOCs may be suitable proxies for childhood exposures for epidemiological analyses of this cohort.

## Chemistry and Exposure Assessment – Posters

**MP102 Energy Dispersive X-ray Spectroscopy Mapping of Particles As A Component of Lichen Biomonitoring in Seattle, Washington**

*G.T. Guddal, Western Washington University; A. Johnson, Western Washington University / Department of Environmental Sciences; J. Miller, Western Washington University; R. Sofield, Western Washington University / Huxley College of the Environment*

The composition of airborne particulate matter (PM) can be used to determine the identity and contribution of overlapping air pollution emissions. One limitation of this technique is the cost of filtering PM at enough locations to give meaningful spatial data. We address this limitation by using *Ramalina farinacea* to collect PM deposition across 9 locations in South Seattle. This was used in tandem with metal bioaccumulation to identify driving factors of air quality in each of the sample sites. Bioaccumulation was measured using sequential extraction of lichen tissue with inductively coupled plasma-mass spectrometry for 24 metals. Particles were characterized using backscatter scanning electron microscopy with energy-dispersive X-ray spectroscopy mapping to determine the size and composition of 17,783 particles. The metal and PM accumulation data were analyzed using positive matrix factorization for source apportionment, which was interpreted with the SPECIATE repository to identify major emission contributions. Our findings demonstrate that lichen can successfully be used to capture PM for electron microscopy analysis, and have identified vehicular emissions as the primary driver of PM trends in South Seattle.

**MP103 Uncertainty estimation of DTT measurement of Oxidative Potential of Ambient Aerosols**

*C. Molina, Facultad de Ciencias / Universidad de Chile / Centro de Ciencias Ambientales; C.A. Manzano, R. Toro, R. Morales, Universidad de Chile / Department of Chemistry; M. Leiva, Centro Ciencias Ambientales / Facultad de Ciencias / Universidad de Chile / Department of Chemistry*

Particle matter (PM) has been linked to adversed health effects even at low concentrations. The most accepted hypothesis describes PM-induced inflammatory processes derived from oxidative stress as a result of the generation of an excess of reactive oxygen species (ROS) and radical species that exceed the availableantioxidant defenses producing cell damage. Thus, oxidative stress represents a relevant mechanism of toxicity derived from PM, and the measurements of the oxidative potential (OP) in PM could be a first step in the elucidation of the subsequent downstream processes. Different assays exist for measuring OP, the most common being the dithiothreitol (DTT) assay, which is currently used in studies for the measurement of oxidative potential (OP) of PM. The present work presents a measurement uncertainty evaluation according to Guide to the Expression of Uncertainty in Measurement (GUM) of the OP by DTT assayin PM10, as measured by UV-VIS Method. The GUM method is not typically used to report uncertainty. In general, the analytical results only report the measurement's standard deviation under repetition as an uncertainty; thus, not all sources of uncertainty are considered. In this work, the major sources of uncertainty regarding the measurements were identified. Acknowledgments.One of the authors (MALG) acknowledges the support of National Commission for Scientific and Technological Research CONICYT/FONDECYT 2016 grant no. 1160617. The authors declare no financial relationships with any organizations that might have an interest in the submitted work; no other relationships or activities that could appear to have influenced the submitted work.

**MP104 Toxic effects of the emissions from burning tyres on abattoir workers in Nigeria**

*F.O. Okonkwo, I.N. Onwurah, University of Nigeria / Biochemistry*

In the bid to reduce the littering of our environment of condemned tyres, they are now highly used as a regular practice for roasting/processing of slaughtered animals such as goats, sheep and cows, especially their edible skin popularly known as "kanda" in the local parlance. Burning tyres release particulate matter, volatile organic compounds (VOCs) and hazardous air pollutants (HAPs) especially polycyclic aromatic hydrocarbons (PAHs) into the environment. PAHs are reported to cause chest pain, respiratory irritation, cough, dermatitis, depressed immune system, a decrease in lung function, and also carcinogenic, following chronic exposures. This study was aimed at evaluating the risk of exposure of abattoir workers (butchers) to emissions from burning tyres during roasting/defurring of cows and goats within the abattoir premises. Specifically the study sought to determine the: (i) concentrations of some selected EPA priority PAHs in ambient air in, and around the abattoir, (ii) concentrations of particulate matter in ambient air in and around the abattoir, (iii) concentrations of some PAH metabolites and some heavy metals in post-shift urine of butchers and control subjects, (iv) spirometric evaluation of lung function, (v) concentration of urinary phenol and (vi) cytogenetic evaluation of DNA damage in buccal exfoliates of butchers. Some of the results show that the concentration of 1-Hydroxypyrene (1-OHPyr) (µg/molCret), a PAH metabolite, in the post-shift urine samples of the butchers was significantly higher, ($P < 0.05$) with mean concentration ±SD value of (0.52±0.13µg/molCret vs 0.20±0.07µg/molCret); urinary phenol concentration, (14.26 ± 1.19 mg/L vs. 4.44 ± 1.12 mg/L); and concentrations of the heavy metals zinc and nickel (0.91±0.19 vs 0.31±0.28 mg/l and 0.11±0.06 vs 0.06±0.02 mg/l, respectively) in exposed butchers when compared with the control which were unexposed administrative staff working in the abattoir respectively. The buccal epithelial exfoliates showed that karyorrhexis and condensed chromatin bodies were significantly higher in the exposed butchers than in the unexposed control.

**MP105 Study on the pollution characteristics of polychlorinated biphenyls in PM2.5 of different cities in China**

*Y. Lu, Q. Wang, National Institute of Environmental Health, China CDC; J. She, Environmental Health Lab / CA Department of Public Health; D. Xu, National Institute of Environmental Health, China CDC*

This study is to evaluate the distribution and concentration of polychlorinated biphenyls in $PM_{2.5}$ , and to monitor the temporal trend, to identify the source of PCBs for providing information to control and manage PCB pollution problem. The samples were collected with filters using high volume sampling in four cities including Shanghai, Beijing, Guangzhou and Harbin from November 2015 to March 2017. The 18 polychlorinated biphenyls (PCBs including 12 coplanar PCB77, 81, 126, 169, 105, 114, 118, 123, 156, 157, 167, 189; and 6 indicator PCB28, 52, 101, 153, 138, 180) were analyzed with high resolution gas chromatography-high resolution mass spectrometry (HRGC-HRMS) based on USEPA 1668C method. The result showed that the mass concentration of PCBs in $PM_{2.5}$ were in the range of 24.0-40.5 pg/m$^3$, the toxic equivalent quantities (TEQs) of PCBs in $PM_{2.5}$ were in the range of 0.105-0.680 fg WHO -TEQ/m$^3$. Compared with studies from large cities in other countries, the concentration of

PCBs is close to the level in Manchester, lower than Chicago and Paris and slightly higher than Tokyo. The distribution and temporal trend of Polychlorinated biphenyls in $PM_{2.5}$ in four cities in China are quite different, and indicator PCBs were the most abundant contributor to the total concentration of PCBs in all cities. Compared the congener profile of the PCBs in $PM_{2.5}$ and the ones from automobile exhaust, emission of combustion of fossil fuel and emission from industry sites, we concluded that automobile exhaust is the main source of PCBs in Shanghai, with relative high level of PCB 28 and 52; The main source of PCBs in $PM_{2.5}$ from Beijing is from the incomplete combustion of fossil fuel consumed in the industry. No clear dominant PCB congener were found from industry sites and the highest PCBs concentration was observed in industrial sites followed by the reference urban sites and residential area. Relative high PCB 118 and 153 in $PM_{2.5}$ from GuangZhou matched the emission profile from waste incineration and burning plastics with chlorine. Concentration of PCBs in $PM_{2.5}$ in Harbinis lower than other three cities. The PCBs level increased in GuangZhou, while decreased in ShangHai and Beijing and no change in Harbin during the monitoring period.

**MP106 Calculation of the sampling rate of PCB congeners using the passive air sampling method (PASM)**

*S. Nagahora, K. Anezaki, Hokkaido Research Organization / Institute of Environmental Sciences*

The sampling rate ($m^3$/day) of the passive air sampling method (PASM) was calculated for measuring the concentrations of PCBs and dioxins (DXNs) in ambient air. Generally, we utilize the active air sampling method (AASM) for monitoring the atmospheric concentrations of PCBs and DXNs. The AASM requires an expensive air sampler and requires electricity, while the PASM is cost-effective and requires no energy. Therefore, the PASM is better suited to monitoring organic pollutants in a wide area than the AASM. We set a flying-saucer-shaped passive air sampler on the rooftop of our laboratory in Sapporo city, Japan. An AASM sampler was set next to the PASM sampler. A quartz fiber filter (QFF), two polyurethane foam plugs (PUF), and an activated-carbon felt disk (ACF) were settled in the AASM sampler, whereas only one PUF was settled in the PASM sampler. The sampling period for the PASM was two months. The PCB concentration was analyzed via high-resolution gas chromatography (HRGC)/high-resolution mass spectrometry (HRMS). Considering the five PASM samples, from April 2017 to January 2018, the total PCB concentrations ranged from 14,000 to 58,000 pg/PUF. The sampling rates of the major PCB congeners by the PASM were calculated in comparison to those of PASM and AASM. The average sampling rates of six PCB congeners were 2.1 $m^3$/day (PCB-11), 3.1 $m^3$/day (PCB-28), 3.7 $m^3$day (PCB-52), 4.5 $m^3$/day (PCB-101), 5.1 $m^3$/day (PCB-153), and 4.8 $m^3$/day (PCB-179). These results were similar to those reported in other countries. Therefore, PASM is suitable for monitoring the concentration of organic pollutants in ambient air in various regions.

**MP107 Characteristics of contamination for HCH and endosulfan in air and soil in the Republic of Korea**

*C. Sangwook, Korea Environment Corporation; L. Changho, Korea Environment Corporation, Chosun University; K. Jinhan, K. Hojung, K. Hyunjung, C. Yongho, K. Minji, J. Suyeon, O. Dahae, G. Minji, S. Goeun, Korea Environment Corporation*

Introduction HCH and endosulfan is an organochlorine pesticides (OCPs) that has widespread use in many parts of the world, including the European Union, Australia, Canada, United States and Republic of Korea. OCPs has been used from 1940s and is effective against a broad number of insect pests and mites. As a result, this pesticide is applied to a wide number of crop types including cotton, fruit trees and plantation crops such as tea and coffee. However, due to its semi-volatility and relative persistence, OCPs is a ubiquitous environmental contaminant occurring in many environmental compartments. This study was performed to understand the actual isomer ratio of HCH and endosulfan in ambient air and soil of Republic of Korea. Materials and methods The air and soil samples were selected at 108 sites. Air samples were collected using high volume air sampler for 24 hours per day for 3 consecutive days with 0.75 m3/min flow rate. Particles on glass fiber filter and gaseous phases in activated carbon felt/polyurethane form were extracted by soxhlet extraction with dichloromethane, toluene and acetone for 24 hours. Soil samples were mixed and collected 100 g as dry weight, and a extracted by soxhlet using toluene for 24 hours. OCPs were cleaned up by florisil cartridge. 1st fraction of cartridge was activated with 10mL of n-hexane and then eluted with 100mL of n-hexane, 2nd fraction with 100mL of n-hexane solution containing dichloromethane (25% vol) was received. HCH and endosulfan were analyzed by HRGC/HRMS. Results and discussion From the results of HCH and endosulfan analysis in air and soil, β-HCH is predominant isomer in the soil. In HCH, β-HCH is the most stable and persistent in soil due to lower vapour pressure than other HCH isomers, which make for β-HCH easier adsorption to the soil and less evaporative loss from the soil. And endosulfan-sulfate is predominant isomer in the soil. These findings are in concordance with the endosulfan metabolic rate. Endosulfan is microbially transformed to the stable and toxic metabolites β-endosulfan and endosulfan-sulfate in the soil due to several factors such as soil type, temperature, moisture and organic carbon content. Also, this study suggests that HCH and endosulfan of contamination were affected by seasonal temperature variations. Because Republic of Korea has four distinct seasons, and the temperature difference between winter and summer is about 40 degress on average.

**MP108 Volatilization and Atmospheric Transport of Chlorpyrifos and Chlorpyrifos Oxon under Field Conditions**

*S. Das, University of Otago / Chemistry; K.J. Hageman, Utah State University / Department of Chemistry and Biochemistry; S. Michelsen-Heath, University of Otago / Department of Zoology; I. Stewart, University of Otago / Department of Chemistry; A. Mercer, University of Otago / Department of Zoology*

Vapor drift occurs when pesticides volatilize from sprayed fields and are blown off-site by the wind, potentially affecting non-target ecosystems. Organophosphate insecticides can travel many kilometers through the atmosphere and due to their toxic and moderately persistent nature, they may incur damage away from the application site. The objective of this work was to better predict the transport and fate of the organophosphate insecticide, chlorpyrifos and its degradation product, chlorpyrifos oxon. To this end, we sprayed a commercial formulation of chlorpyrifos on a field of Purple Tansy (*Phacelia tanacetifolia*) at a farm near Ida Valley, Central Otago, New Zealand in January 2017. Air samples were collected using one high-volume air sampler (HVAS) and seven low-volume, battery-powered active air samplers (LVASs). Air samplers were run for 6 hours per sample and were deployed in a grid around the field and along a transect extending up to 500 m away from the sprayed field. Sampling took place for 21 days after spraying. Soil samples were also collected from inside and outside the sprayed field throughout the study period. We quantified chlorpyrifos and its oxon in the air and soil samples and used temperature, relative humidity, wind direction and precipitation to understand the concentration trends with time and space. Chlorpyrifos was detected every day of the sampling period, with concentrations decreasing significantly following three days after spraying. Chlorpyrifos oxon was only detected in samples from the HVAS within the first three days of spraying. Precipitation and rainfall played an important role in controlling the measured concentrations. Chlorpyrifos volatilization rates from the field were calculated with a pesticide volatilization model and the characteristic travel distance (CTD) of chlorpyrifos was calculated using the ELPOS (Environmental Long-range Transport and Persistence of Organic Substances) model, enabling generation of modeled pesticide concentrations over space and time. Measured chlorpyrifos concentrations were also compared to those generated with the SCREEN3 model, a screening version of the Industrial Source Complex Dispersion Models (ISC3). Results from this work are useful in predicting the distances and time after spraying at which chlorpyrifos drift can cause potential harm to non-target organisms.

**MP109 Impact of Simulated California Rice-Growing Conditions on Chlorantraniliprole Partioning**

*Z. Redman, R.S. Tjeerdema, University of California, Davis / Environmental Toxicology*

Chlorantraniliprole (3-Bromo-N-[4-chloro-2-methyl-6-(methylcarbamoyl) phenyl]-1-(3-chloro-2-pyridine-2-yl)-1H-pyrazole-5-carboxamide; CAP; water solubility 1.023 mg?$L^{-1}$) was recently registered for application on California rice fields. Air- and soil-water partitioning of CAP were investigated under simulated California rice field conditions through calculation of $K_H$ and ?$_{aw}$H and a batch equilibrium method following OECD 106 guidelines, respectively. $K_H$ and ?$_{aw}$H were determined to be 1.69x$10^{-16}$ – 2.81x$10^{-15}$ atm?$m^3$?$mol^{-1}$ (from 15 – 35 °C) and 103.68 kJ?$mol^{-1}$ respectively. Log($K_{oc}$) ranged from 2.59 – 2.96 across all soil and temperature treatments. Log($K_F$) ranged from 0.61 – 1.14 across all soil, temperature and salinity treatments. Temperature and salinity increased sorption significantly at 35 °C ($P < 0.05$) and 0.2 M ($P < 0.0001$) respectively, while soil properties impacted sorption across all treatments. Overall results, corroborated using the Pesticides in Flooded Applications Model, indicate that volatilization of CAP is not a major route of dissipation and sorption of CAP to California rice field soils is moderately weak and reversible. DOI:10.1021/acs.jafc.7b05775

**MP110 Photochemical Degradation of Polyhalogenated Carbazoles in Hexane by Sunlight**

*S. Zhou, Zhejiang University of Technology / College of Environment; X. Pan, University of Illinois at Chicago / School of Public Health; Q. Tang, Zhejiang University / College of Environmental and Resource Sciences; H. Zhu, Zhejiang University of Technology / School of Environment; L. Zhao, Zhejiang University / College of Environmental and Resource Sciences; J. Guo, Indiana University, Bloomington / School of Public Health; Z. Wang, Nanjing University / School of Environment; W. Liu, Zhejiang University / College of Environmental and Resource Sciences; A. Li, University of Illinois at Chicago / School of Public Health*

Polyhalogenated carbazoles (PHCZs) are a class of halogenated dibenzopyrrole. In recent years, they have been increasingly detected in the environment and found to be bioaccumulative and potentially toxic. However, their environmental transformation potential is largely unknown. In this study, the UV absorption spectra with wavelength range 200-500 nm were obtained for unsubstituted carbzaole (CZ) and 10 individual chlorinated (3-CCZ, 1368-CCZ, 2367-CCZ), brominated (3-BCZ, 27-BCZ, 36-BCZ, 136-BCZ, 1368-BCZ), and mixed halogenated (1-B-36CCZ, and 18-B-36-CCZ) PHCZ congeners in hexane. In addition, individual hexane solutions were prepared in clear glass vials for CZ and these PHCZs as well as a sediment extract involving 9 other PHCZs for which the molecular formulas were determined but the halogen substitution positions remain unknown. The solutions were exposed to natural sunlight along with corresponding controls in amber glass vials, to investigate the kinetics and pathways of PHCZ photodegradation. All targeted compounds decomposed rapidly under solar irradiation, which indicates that photolysis is a possible route of environmental loss of PHCZs. The pseudo-first-order reaction rate constants ($k$) of these PHCZs varied from 0.183 $h^{-1}$ to 2.394 $h^{-1}$, and increased exponentially with an increasing number of chlorines and bromines in PHCZ molecules. A predictive equation was obtained by multi-variant linear regression of ln $k$ with the numbers of bromine and chlorine as independent variables, which showed that contribution to ln $k$ from each bromine atom is more than doubling of that from each chlorine atom. Iodine-containing PHCZs decompose more rapidly than those without iodine, suggesting the loss of iodine is rapid and likely to be the first step. The occurrence of stepwise debromination was confirmed by examining the reaction products for six PHCZs containing bromines. To quantitatively determine the contribution of dehalogenation to the total photolytic degradation, we adopted a kinetic model for simplified parallel reactions. The modeling results indicated that debromination contributed only 20% to 51% of the total loss of the parent PHCZs. Further research is needed to identify and quantify the contributions of other photolytic degradation routes of PHCZs in hexane.

**MP111 Adaption and use of an inexpensive quadcopter of targeted sampling of mercury and VOCs in the atmosphere**

*A. Scircle, O. Black, University of Mississippi; J. Cizdziel, University of Mississippi / Chemistry*

We modified a popular and inexpensive quadcopter to collect gaseous mercury (Hg) on gold-coated quartz cartridges, and analyzed the traps using cold vapor atomic fluorescence spectrometry. For VOCs we conducted active sampling on sorbent tubes outfitted to the quadcopter and analyszed them by thermal desorption (TD) gas chromatography-mass spectrometry (GC-MS). The aerial sampling method permits for the simultaneous collection of multiple air samples on separate tubes concurrently, increasing sample throughput compared to single canister sampling. Furthermore, the method is relatively inexpensive when compared to similar approaches, with overall costs below about $2000 (U.S. dollars). Flight times averaged 16 minutes, limited by battery life, and yielded >5 pg of Hg, well above the limit of detection (< 0.2 pg). We measured progressively higher concentrations upon both vertical and lateral approaches to a dish containing elemental Hg, demonstrating that the method can detect Hg emissions from a point source. Using the quadcopter, we measured atmospheric Hg near anthropogenic emission sources in the mid-south USA, including a municipal landfill, coal-fired power plant (CFPP), and a petroleum refinery. Average concentrations (± standard deviation) immediately downwind of the landfill were higher at ground level and 30 m compared to 60 m and 120 m (5.3 ± 0.5 ng $m^{-3}$, 5.4 ± 0.7 ng $m^{-3}$,4.2 ± 0.7 ng $m^{-3}$, and 2.5 ± 0.3 ng $m^{-3}$, respectively). Concentrations were also higher at an urban/industrial area (Memphis) (3.3 ± 0.9 ng $m^{-3}$) compared with a rural/background area (1.5 ± 0.2 ng $m^{-3}$). For VOCs, we measured at several heights near anthropogenic sources in the mid-south USA, including a municipal landfill, petroleum refinery, and a coal fired power plant (CFPP), and within the canopy of a loblolly pine (*Pinus taeda*) forest. Concentrations of benzene, toluene and xylene (BTX) were higher ($p< 0.05$) downwind of the refinery and CFPP compared to upwind. We observed both a unique mixture of VOCs at each site and higher concentrations of abundant VOCs downwind compared to upwind of the point sources, and within versus above the forest canopy. Overall, this feasibility study demonstrates that highly maneuverable multicopters can be used to probe Hg and VOC concentrations aloft, and thus have great potential to be utilized in unique sampling situations and for vertical profiling.

**MP112 Testing the Use of Wastewater Tracers as Predictors of Pharmaceutical Distributions in The Long Island Sound Estuary**

*M.G. Cantwell, USEPA; D.R. Katz, Office of Research and Development / USEPA, Narragansett / Atlantic Ecology Division; J.C. Sullivan, ORISE at USEPA / AED; M. Lyman, CT DEEP*

Urban estuaries such as Long Island Sound (LIS) receive large volumes of treated effluents from numerous municipal wastewater treatment facilities. These effluents contain many classes of contaminants including pharmaceutical compounds. In this study water was sampled for 16 highly prescribed pharmaceuticals at 17 sites along the Long Island Sound (LIS) estuary and at the river mouths of four of its major tributaries in Connecticut. Pharmaceutical concentrations were highest in western LIS, ranging from non-detect to 71 ng/L and declined steadily eastward, while river samples ranged from non-detect to 83 ng/L. Two wastewater tracers were tested, sucralose and caffeine, with both accurately predicting pharmaceutical behavior in LIS, while only sucralose performed well at the river sites. Sucralose also correlated well with salinity in LIS, exhibiting conservative behavior along the transect. Attenuation coefficients were determined for measurable pharmaceuticals present in the water column and compared against sucralose to estimate the magnitude of decline in concentrations that may be attributable to in situ degradation. The results provide further evidence of sucralose's effectiveness as a tracer of wastewater-borne contaminants under estuarine conditions.

**MP113 Survey on Chemical Substances used in Daily Life by Target Screening using SPE-LC-Q/TOFMS at Sewage Treatment Plants in Japan**

H. Iida, Tokyo Metropolitan Institute of Public Health; T. Suzuki, K. Watanabe, Tokyo Metropolitan Institute of Public Health / Division of Environmental Health; H. Konishi, Tokyo Metropolitan Institute of Public Health; S. Nagahora, R. Tahara, Hokkaido Research Organization, Institute for Environmental Science; T. Orihara, Sapporo City Institute of Public Health; K. Iwabuchi, Iwate Prefectural Research Institute for Environmental Sciences and Public Health; F. Adachi, S. Takagi, Osaka Institute of Public Health; T. Miyawaki, Fukuoka Institute of Health and Environmental Sciences; K. Kadokami, The University of Kitakyushu

For counteracting chemical pollution in water environments, it is necessary to determine the environmental concentration and characterize the generation and discharge of the pollutant itself. However, because many products are used in daily life, it is often difficult to ascertain the origin of some common pollutants. In urban areas, common chemicals collect in sewage treatment plants (STPs). Thus, we focused on determining the amount of generation and discharge of specific chemicals by monitoring at STPs. We monitored a total of 8 STPs in Japan and water samples were collected as 24 h composites of the influent and effluent at each STP in the summer and winter of 2017–2018. In this study, 492 substances were analyzed by target screening method using SPE-LC-Q/TOFMS. Daily generation and discharge units (µg/day/1000 people) were calculated as follows: concentration of substance in the influent (or effluent) (ng/L) × volume of the influent (or effluent) ($m^3$/day) / population (1000 people). A total of 126 substances were detected in the influent and 138 substances in the effluent during the summer survey, and 106 substances in the influent and 118 substances in the effluent during the winter survey. During the both seasons, pharmaceuticals were frequently detected. The total number of the detected substances in the summer survey was greater than that in the winter survey because more pesticides were detected in summer than in winter. The generation units of metformin (diabetes drug), sucralose (artificial sweetener), theophylline (bronchodilator), theobromine, FB351 (UV absorber), and FB71 (fluorescent bleach) were relatively high during both seasons. The generation of theobromine, FB351, and N,N-dimethyl dodecylamine N-oxide (DDAO) was higher in winter than in summer. For metformin and sucralose, the discharge at all STPs were relatively high during both seasons, and their removal rates were relatively low at 67% and 12% in summer, and 71% and 2% in winter, respectively. In both seasons, DDAO showed the largest differences in generation of all detected substances among the STPs. This survey at the STPs using the target screening method with SPE-LC-Q/TOFMS allowed for the clarification of the generation and discharge of pollutants in urban areas, and their removal rates at the STPs.

**MP114 Personal daily discharge unit (DDU) evaluation of various chemicals**

S. Nagahora, R. Tahara, Hokkaido Research Organization / Institute of Environmental Sciences; T. Orihara, Sapporo City Institute of Public Health; K. Iwabuchi, Iwate Prefectural Research Institute for Environmental Sciences and Public Health; H. Iida, T. Suzuki, Y. Kosugi, Tokyo Metropolitan Institute of Public Health; K. Watanabe, Tokyo Metropolitan Institute of Public Health / Division of Environmental Health; H. Konishi, Tokyo Metropolitan Institute of Public Health; S. Takagi, F. Adachi, Osaka Institute of Public Health; T. Miyawaki, T. Miyawaki, Fukuoka Institute of Health and Environmental Sciences

In this study, we have quantitatively investigated the daily discharge of personal contaminants like pharmaceuticals, cosmetics, fragrances, tobacco smoke, etc. After intake, these chemicals are excreted and released from the human body to a municipal sewage treatment plant (MSTP). We were interested in the average discharge of each chemical through life activities. Therefore, we collected influent water samples from eight sewage treatment plants in Japan. Approximately 1000 substances were analyzed by gas chromatography/mass spectrometry (GC/MS) and liquid chromatography/quadrupole time-of-flight mass spectrometry (LC/QTOF-MS). Approximately 30% and 26% of these analyzed chemicals were detected in the influent, respectively. We then calculated the personal daily discharge unit (DDU) (micrograms/day/1000 persons) for each detected substance, based on the inflow volume and the population associated with each MSTP. To verify the appropriateness of the inflow samples, we calculated the composition patterns of 12 sterols and the percentages of coprostanol and 24-ethylcoprostanol, which are molecular indicators of human feces. The relative contents of coprostanol and 24-ethylcoprostanol were ~21% and 6% in samples collected in summer and autumn, respectively. Furthermore, the average DDU values of coprostanol and 24-ethylcoprostanol were 456 and 125 mg/1000 persons/day at 7 MSTPs, respectively. Approximately 4-times higher DDU values (2012 and 594 mg/1000 persons/day, respectively) were detected at the eighth MSTP, probably due to a large-scale introduction of commuters into the connected area of the eighth MSTP in the daytime. High DDU values were obtained for both fecal sterols and some pharmaceuticals at this MSTP. However, for some chemicals used externally, such as fragrances and dermal pharmaceuticals, no differences in DDU value were observed among the MSTPs, implying that externally used chemicals were discharged mainly by the washing of the body and clothes. Thus, these chemicals were discharged mainly from home bathrooms or laundries rather than office toilets.

**MP115 Estimation of emission amounts of 970 chemicals from human activities in Japan**

R. Tahara, S. Nagahora, Hokkaido Research Organization / Institute of Environmental Sciences; T. Orihara, Sapporo City Institute of Public Health; K. Iwabuchi, Iwate Prefectural Research Institute for Environmental Sciences and Public Health; H. Iida, Tokyo Metropolitan Institute of Public Health; T. Suzuki, Tokyo Metropolitan Institute of Public Health / Division of Environmental Health; Y. Kosugi, Tokyo Metropolitan Institute of Public Health; K. Watanabe, Tokyo Metropolitan Institute of Public Health / Division of Environmental Health; H. Konishi, Tokyo Metropolitan Institute of Public Health; S. Takagi, F. Adachi, Osaka Institute of Public Health; T. Miyawaki, Fukuoka Institute of Health and Environmental Sciences; K. Kadokami, The University of Kitakyushu

The number and volume of chemicals used daily have been rapidly increasing owing to a greater desire for a comfortable and healthy life. As these chemicals are used in various commercial products, it is essential to understand their emissions and sources to establish measures to reduce their environmental impacts. To estimate the amount of emission and discharge of 970 chemicals into the environment, we examined these chemicals in eight wastewater treatment plants (WWTPs) in major cities in Japan thrice a year by using the Automated Identification and Quantification Database System with gas chromatography-mass spectrometry. Although the total concentrations ranged from 470 to 1600 µg/L, there was no regional difference and seasonal variation in the composition of the chemicals detected in the influents of the eight WWTPs. The dominant chemicals in the influents were sterols (60% of the total concentration), including cholesterol (33%), caffeine (5%), squalene (4%), and L-menthol (2%), which are used in daily life. Further, n-paraffins, which are present in light oil and heavy oil, were detected, indicating the contribution of factories. Since the proportions of the dominant chemicals in the influents were almost the same, their concentrations can be used to estimate the amount emitted in Japan. To confirm this, we compared the amount of di(2-ethylhexyl)phthalate (DEHP) emitted based on calculations using the concentrations with the amount of inflow in WWTPs reported by the Ministry of Economy, Trade and Industry because DEHP is designated as a Pollutant Release and Transfer Register (PRTR) substance. The annually emitted amounts based on the calculations and the PRTR were 200±67 and 118 tons, respectively, which are almost similar. In the case of phenol, which is also designated as a PRTR substance, the annually emitted amounts were 35±31 and 16 tons, respectively, which are also similar like in the case of DEHP. This indicates that this calculation method, which uses concentrations, can be applied to all target substances including those that are not designated as PRTR substances. Nevertheless, the estimated annual discharge of DEHP based on calculations using its concentrations in discharged waters was 35±36 tons, while that reported in the PRTR is 1.2 tons. The gap between these values indicates that further studies are necessary to achieve a more accurate estimation of the amounts of chemicals discharged from WWTPs to the aquatic environment.

**MP116 Discharge scenario of perfluoroalkyl acids into the environment via sewage treatment plants**

*K. Iwabuchi, Iwate Prefectural Research Institute for Environmental Sciences and Public Health; S. Nagahora, R. Tahara, Hokkaido Research Organization / Institute of Environmental Sciences; T. Orihara, Sapporo City Institute of Public Health; H. Iida, Tokyo Metropolitan Institute of Public Health; T. Suzuki, K. Watanabe, K. Watanabe, Tokyo Metropolitan Institute of Public Health / Division of Environmental Health; H. Konishi, Tokyo Metropolitan Institute of Public Health; S. Takagi, F. Adachi, Osaka Institute of Public Health; T. Miyawaki, Fukuoka Institute of Health and Environmental Sciences; K. Kadokami, The University of Kitakyushu*

Perfluoroalkyl acids (PFAAs) are detected throughout the world, and thus some of them have been designated as persistent organic pollutants. Although understanding their emission loads and sources are essential to establish measures against their environmental impacts, they are yet to be clarified. PFAAs are used in various commercial products, and therefore small amounts are usually found in wastewater discharged from factories and households, which are typically treated in sewage treatment plants (STPs). Almost the entire volume of wastewater generated due to human activities in urban areas of Japan is treated by STPs. Therefore, we examined PFAAs in STPs located in major cities to determine the amount of PFAAs generated due to human activities. We selected eight STPs (designated as STP A-H) in Japan. Influents and effluents were collected three or four times during the period from February 2017 to February 2018. PFAAs in a 24-h composite sample were extracted by solid-phase extraction, and then measured by LC-MS/MS. The target compounds were 15 different PFAAs (hereinafter, CXA means carboxylic acid type, CXS means sulfonic acid type, and X signifies the carbon number). There were remarkable differences in PFAA concentrations among the STPs examined; PFAA concentrations in the influent and effluent of STP D and those in the effluent from STP G were significantly higher than those of other STPs. The concentrations of PFAA in the influents and effluents were compared. Concentrations of C5A to C9A in effluents were higher than in influents of almost all STPs, while those of C10A to C13A in effluents were lower than in influents. However, perfluoroalkyl sulfonic acid (PFSA) concentrations in effluents were lower than those in influents for all the STPs, except STP G. During water treatment processes, C10A to C13A, and some PFSAs seemed to be removed through adsorption on activated sludge, while C5A to C9A were formed from their parent substances. The loads of PFAA, emitted due to human activities and discharged from the STPs, were calculated using the detected concentrations, volume of wastewater, and population served by the sewer. Based on the median calculated amounts, the amount of PFAA released in Japan was calculated to be 800 kg/y (amount of C8S released was the highest: 210 kg/y), and amount of PFAA discharged from STPs in Japan was calculated to be 810 kg/y (C8S was discharged in the highest quantity: 190 kg/y).

**MP117 Characterization of hexavalent chromium and total chromium in drinking water monitoring data**

*G. Brorby, C. Ring, F. Loko, M.A. Harris, ToxStrategies, Inc*

In 2014, the State of California promulgated a maximum contaminant level (MCL) for hexavalent chromium [Cr(VI)] of 10 µg/L, as compared to the MCL for total chromium of 50 µ/L. Although the California MCL for hexavalent chromium is no longer in effect as a result of a court decision, its adoption created immediate interest because hexavalent chromium had been reported in public drinking supplies in California at concentrations exceeding 10 µg/L, but rarely above 50 µg/L. Since that time, a substantial amount of data (over 60,000 samples) on Cr(VI) and total chromium concentrations in public water systems (PWSs) nationwide has been collected as part of the Third Unregulated Contaminant Monitoring Rule (UCMR3). From these data, the Cr(VI) concentration was less than 10 µg/L in approximately 97.6% of groundwater samples and in >99.6% to 100% of other samples (surface water, mixed surface water/groundwater; groundwater directly influenced by surface water). In California, the percentages were approximately 93.9% and >99.2% to 100%, respectively. The total chromium concentration was less than 50 µg/L in >99.8 to 100% of all sample types whether evaluated nationwide or California alone. Compared to the Federal MCL for total chromium of 100 µg/L, 100% of the Cr(VI) concentrations and all but one of the total chromium concentrations were less than 100 µg/L. To evaluate the geographical distribution of higher Cr(VI) and total chromium concentrations, UCMR3 sample locations were estimated for each PWS as the centroid of all ZIP codes that the PWS reported serving (exact locations are not publicly available for security reasons). Using these estimated sample locations, PWSs with higher concentrations of Cr(VI) and total chromium tended to cluster regionally in California, as well as in Arizona and Oklahoma. This analysis could serve as a basis for further investigation of geospatial occurrence or sources of Cr(VI) and total chromium in drinking water.

**MP118 Surface Water Impact from California Cannabis Cultivation**

*A. Narzynski, J. Teerlink, California Department of Pesticide Regulation / Surface Water Protection Program; R. Kubiak, California Department of Pesticide Regulation*

Cannabis cultivation may to lead to a substantial increase in pesticide use and subsequent impact to surface water through off-site transport from both indoor and outdoor growing operations. Since January 2018, California's Bureau of Cannabis Control has established residue testing for manufactured cannabis products based on human health concerns. Further investigation is necessary to understand potential environmental impacts. Pesticide use patterns and subsequent off-site transport from cannabis cultivation are poorly understood. The California Department of Pesticide Regulation's Surface Water Protection Program will conduct an environmental monitoring study to evaluate the impacts of legal cannabis cultivation on surface water environments. Site selection will focus on prevalence of grows resulting from local ordinances, cultivation licenses, and water discharge pathways (i.e., wastewater and surface water). Pesticides prioritized for analysis will be selected based on potential for adverse impacts to surface water biological communities and anticipated prevalence in the regulated industry.

**MP119 Optimization of Sampling Design to Determine the Spatial Distributions of Emerging Contaminants in Estuaries**

*D.R. Katz, Office of Research and Development, USEPA, Narragansett / Atlantic Ecology Division; A. Kuhn, USEPA / ORD / NHEERL / Atlantic Ecology Division; J.C. Sullivan, ORISE at USEPA / AED; M.G. Cantwell, Office of Research and Development, USEPA, Narragansett / Atlantic Ecology Division*

Narragansett Bay (NB) is New England's largest estuary and has been the location of numerous multi-disciplinary scientific studies over the last several decades. Most spatial research conducted within NB to date has employed deterministic sampling designs. Several studies have used probabilistic sampling designs on portions of NB; however, a randomized, probabilistic sampling design has seldom been applied to the whole estuary. In this study, a sampling design was developed to implement a probabilistic sampling approach to examine the distribution of emerging contaminants in the estuary. Existing high-density salinity data from the upper portion of NB was used for optimization of the sampling design and results from this analysis were applied to the whole estuary. Five spatial geostatistical interpolation kriging models were compared and the empirical bayesian kriging (EBK) model performed best across the estuary. The results from this analysis were used to determine an optimum number of stations (n=67) and sampling density (0.2 stations/km$^2$) across the estuary. Stations were chosen randomly within a randomized, tessellated hexagonal grid and samples were taken to measure the concentrations of a suite of pharmaceutical compounds. Spatial models using EBK were generated at varying spatial densities from the full number of sampled stations to ¼ the number of stations. Error statistics for each spatial density were generated using cross-validation between predictions and measurements. These statistics were compared using the Derringer desirability function approach. While models were developed for each compound at each spatial density, sucralose was used as a model compound. Results of the desirability comparison indicated that the performance of the spatial model was very accurate at predicting spatial distributions with the full set of samples and that only half of the sites were sufficient to develop a spatial model for NB with only a minor decrease in accuracy compared to the full number of stations. The findings demonstrate the successful use of this geostatistical spatial modeling framework and indicate its potential suitability for use across similar environments.

**MP120 Occurrence of Pyrethroids in Agriculturally Impacted Surface Waters of California**

*S. Wagner, California Department of Pesticide Regulation; X. Deng, California EPA / Surface Water Protection Program*

The California Department of Pesticide Regulation's (DPR's) Surface Water Protection Program (SWPP) conducts routine monitoring of surface waters impacted by agricultural pesticide applications. Monitoring efforts target high-use agricultural regions guided by DPR's Pesticide Use Reporting (PUR) database and the aquatic toxicity properties of pesticides. Notably, pyrethroids have been detected frequently and at concentrations that exceed the chronic USEPA aquatic life benchmark for invertebrates. For example, the pyrethroids bifenthrin, permethrin, and lambda-cyhalothrin were detected in more than 60%, 30%, and 20% of samples, respectively, between 2011 and 2016 among all monitoring sites in Salinas, Calif. The chronic USEPA aquatic life benchmarks for invertebrates are in the low parts per trillion concentration range for each of these pyrethroids and were exceeded in more than 90% of the samples from this region. Further, the persistence of pyrethroids in sediment contributes to the observed detection frequencies. The water-sediment half-life of bifenthrin is more than six times greater than that of permethrin. Frequent detections and exceedances of toxicity threshold merit a more detailed analysis of pesticide use patterns on commodities with common pyrethroid use in order to suggest effective best management practices or other mitigation measures.

**MP121 Distribution and Toxic Potential of Pyrethroids, Alkylphenols, and Nonylphenol Ethoxylates in Minnesota Lake Sediments**

*J.L. Crane, Minnesota Pollution Control Agency / Environmental Analysis & Outcomes Division*

Pyrethroids are the third most applied group of insecticides worldwide and are used for both agricultural and urban applications. These compounds are of concern because they are extremely toxic to fish and non-target benthic invertebrates, and this toxicity increases with colder water temperatures. Bifenthrin and permethrin are the major pyrethroid compounds sold in Minnesota, and most of the bifenthrin sales are for crop chemicals. Alkylphenols (APs) are breakdown products of high production alkylphenol polyethoxylates like nonylphenol ethoxylates (NPEs). These compounds are of concern due to their toxicity, estrogenic properties, and widespread environmental contamination. Sediment data on the distribution of these compounds in Minnesota's waterways are sparse. To this end, a project was conducted to address the broad management question of "What are the environmental impacts of these contaminants in Minnesota lake sediments?" This study capitalized on the random sampling design, field sampling assistance, and logistical resources of the USEPA's National Lakes Assessment (NLA) project during the summer of 2017. Thirty of the 50 Minnesota NLA lakes selected for this study targeted lakes in agricultural watersheds, plus lakes in other major land use groups to provide broad geographic coverage. Surficial sediment samples (0-5 cm) were collected from the deepest area of each lake, composited, and split from other samples utilized for NLA conventional analytical parameters. The Minnesota Pollution Control Agency funded the analyses of pyrethroids (and pyrethrins), APs, and NPEs by SGS AXYS Analytical Services Ltd. Several samples had challenging matrix interferences that increased the reporting limits. The Kaplan-Meier means were 12.3 ng/g dw for 4-nonylphenol (53.3% NDs), 11.5 ng/g dw for 4-nonylphenol monoethoxylates (73.3% NDs), and 1.5 ng/g dw for bifenthrin (73.3% NDs). Resmethrin and 4-nonylphenol diethoxylates were each detected in one lake. The other pyrethroids and 4-n-octylphenol were not detected in any of the lakes. Specific GIS-watershed data are currently being obtained. The results will be used to calculate pyrethroid Toxic Units for benthic invertebrates, to make comparisons to available sediment quality guidelines, to possibly compare results of 4-nonylphenol by major watershed land uses, to calculate background threshold values for data with < 80% nondetects, and to compare the results with data from other North American sediments.

**MP122 Pesticides in Washington State Sediments**

*A. Nickelson, Washington State Department of Agriculture / Directors Office; G.R. Tuttle, Washington State Department of Agriculture / Natural Resources Assessment Section*

The Washington State Department of Agriculture (WSDA) has been actively conducting surface water monitoring for pesticides in Washington State since 2003. In 2015 staff developed a pilot study to monitor for pesticides in in streambed sediments with the goal of assessing the need for more routine sediment monitoring by estimating the potential risks to benthic invertebrates from exposure to the pesticides that were found in the stream bed sediments. Stream bed sediments were collected during three separate sampling events at five of the regular WSDA surface water monitoring locations. Thanks to ongoing work being conducted by a collection of municipal stormwater permitees who collaborate under the western Washington municipal stormwater permit, stream bed sediments were also collected at an additional 81 sites around the greater Puget Sound region. The land use characteristics in the watersheds where the sampling locations were located varied between dominantly agriculture and dominantly urban. Each of the 93 samples were analyzed for 126 pesticide compounds and total organic carbon (TOC). All samples collected between March and October of 2015, the typical pesticide application season. There were a total of 45 detections of 12 unique compounds. The most frequently detected compounds were DDT, DDT degradates and bifenthrin. TOC normalized concentrations were compared to previously published Likely Effect Benchmarks (LEB) to assess toxicity to benthic invertebrates. Bifenthrin is an insecticide that is commonly found in household and agricultural products and was the most commonly detected pesticide. In 81% of the samples containing bifenthrin its TOC normalized concentration was found to be above the LEB, indicating high probability of adverse effects on benthic invertebrates. The results of the study indicate that further investigation is warranted due to the presence of pesticides in streambed sediments at levels that may affect benthic invertebrate communities. Plans to resume and possibly expand sediment monitoring for pesticides are planned following laboratory method development that is being implemented to combat the low detection frequencies and high reporting limits encountered in this study.

**MP123 Quantification of pharmaceuticals, personal care products, and perfluoroalkyl substances in sediments from two urban bays, Puget Sound, WA**

*M. Dutch, WA State Department of Ecology / Environmental Assessment Program; S. Weakland, V. Partridge, Washington State Department of Ecology*

Pharmaceuticals and personal care products (PPCPs) and perfluoroalkyl substances (PFASs) are identified as chemicals of emerging concern (CECs) in Puget Sound, WA, due to their potential to cause adverse toxicological, biological, and ecological effects when unintentionally discharged to the environment. Characterization of sources, transport patterns, and the fate of CECs in the environment has been prioritized as part of the toxics monitoring strategy for the Sound. To this end, concentrations of PPCPs and PFASs have been measured and detected in influent, effluent, and biosolids from municipal wastewater treatment plants; in the tissue of invertebrates, fish, birds, and marine mammals; and in surface sediments from ten long-term monitoring stations and from stations in Bellingham Bay and Elliott Bay. Continuing the series of assessments in Puget Sound's urban bays, sediments were tested for the presence of 119 PPCPs and 13 PFASs in Commencement Bay in 2014 and in Bainbridge Basin in 2015. Analyses were conducted for PPCPs and PFASs by AXYS Analytical Services Ltd., Sidney, BC, Canada, using AXYS Method MLA-075, based on EPA 1694 and MLA-041, respectively. These methods use liquid chromatography coupled with tandem mass spectrometry (LC/MS/MS). Results are summarized and presented graphically to indicate the concentration and distribution of PPCPs and PFASs in these Puget Sound urban sediments, with comparisons made to concentrations measured in previous Puget Sound surveys.

**MP124 Presence and sources of drugs, steroids and xenoestrogens in water and sediments from the tidal freshwater Potomac River**

*A. Leahigh, George Mason University / Chemistry and Biochemistry; T.B. Huff, George Mason University / SRIF; G. Foster, Chemistry and Biochemistry*

Selected micropollutants, including endocrine modulators, illicit drugs, therapeutic drugs, detergents, sun screen agents, and parabens were measured in water and riverbed sediments (2017 and 2018) in a tributary embayment of the tidal freshwater Potomac River (Hunting Creek, Alexandria, VA, USA) in the vicinity of an urban wastewater treatment plant (WTP). The aquatic samples were analyzed by using solid phase extraction (water) and QuEChERS (sediment) in combination with liquid chromatography/tandem mass spectrometry. The micropollutants were detected in water at concentrations ranging from 450 to 6 ng/L. Steroid hormones, trimethoprim, and dextromethropham were the most frequently detected constituents in water. In sediment, micropollutant concentrations ranged from 350 to 8 ng/g dwt, with progesterone, dextromethorpham, bisphenol A and prednisone being the most abundant. The geospatial distribution of the micropollutants in Hunting Creek indicated the steroids correlated with spatial proximity to WTP discharge in water and sediments, but the proximity associations were tentative in Hunting Creek given the complex nature of urban emissions and hydrodynamics of a large urban tidal river. Source apportionment using principal components analysis coupled with partial least squares was used to quantify the importance of several identified emission sources. There were multiple sources that could be attributed to the micropollutants found in Hunting Creek, most notably combined sewer outfall discharge and WTP effluent. Apportionment results showed that emission sources for micropollutants can be difficult to identify in large rivers adjacent urban centers where a wide variety of potential emission sources exist.

**MP125 Documenting Ambient PAH Concentrations in California**

*A. DaSilva, B.M. Duke, D. Orr, C. Perez, R.M. Donohoe, B.M. Joab, M.J. Anderson, California Department of Fish and Wildlife / Office of Spill Prevention and Response*

Natural Resource Trustees (California Department of Fish and Wildlife, Office of Spill Prevention and Response, the National Oceanographic & Atmospheric Administration, the US Fish & Wildlife Service, and the Bureau of Land Management) in conjunction with Chevron, have jointly completed Ephemeral Data Collection Plans (EDCPs) for Chevron's marine terminal in Eureka, lightering station near San Diego, and refineries in El Segundo and Richmond, California. Each EDCP includes sampling protocols for environmental media (e.g., water, sediment, and tissue), pre-determined sampling sites, and contact information for first responders, consultants, and laboratories. Samples were collected near the Eureka Terminal and El Segundo Refinery over multiple years and ambient concentrations of polycyclic aromatic hydrocarbons (PAHs) were measured using modified EPA methods. Results show PAH profiles and concentrations vary between sampling years at each site. This is likely due to environmental factors including tidal changes, weather, land use, and petroleum release that are in constant fluctuation and can influence detections overtime. Results also show that PAH profiles and concentrations vary between sampling media. Sediment and tissue samples had measurable concentrations of PAHs such as phenanthrene, flouranthene, and pyrene, whereas PAHs in water samples were often not detected. PAHs in sediment and tissues are often more representative of ambient concentrations due to their affinity to adsorb and bioaccumulate PAHs. Whereas PAH detections in water are often sporadic due to their low water solubility and high affinity for particulate matter. Chemistry results of collected samples has provided valuable ambient data and continual monitoring will provide a better understanding of PAH concentrations at pre-determined sites. This data will help establish pre-spill reference conditions in the event of a petroleum release near or at the sampled sites.

**MP126 Production and Certification of a New Sediment Reference Material: Standard Reference Material 1936 Great Lakes Sediment**

*J.R. Kucklick, K. Huncik, J. Reiner, National Institute of Standards and Technology / Chemical Sciences Division*

The National Institute of Standards and Technology provides many types of natural matrix Standard Reference Materials (SRMs) certified for organic and inorganic contaminants. The materials can be used by laboratories as control samples, to validate methods, assign values to in-house control materials or to measure new contaminants without certified values. SRMs are available for many different matrices including soil, fish, mussel tissue, air particulate matter, house dust, sewage sludge, human blood and sediment. NIST currently has two estuarine sediment materials: SRM 1944 New York/New Jersey Waterway Sediment and SRM 1941b Organics in Marine Sediment. The materials have been certified for polychlorinated biphenyl congeners (PCBs), polycyclic aromatic hydrocarbons (PAHs), polybrominated diphenyl ether congeners (PBDEs), chlorinated pesticides, perfluorinated alkyl substances (PFAS) and trace elements. SRM 1936 is being produced to augment this suite of sediments by providing a contemporary fresh water material from an urbanized location in Great Lakes. SRMs 1941b and 1944 are higher in sulfur and were collected over 20 years ago. For SRM 1936, 480 kg of surficial sediment was collected from Milwaukee Harbor, air dried, milled, radiation sterilized and then bottled. The material will be certified for PAHs, trace elements and value assigned for a variety of other organic contaminants including PCBs, PBDEs and PFAS.

**MP127 Release and Transport of Soluble Phosphate-P from Sediments, Soils and Senescent Leaf Fragments in the W. Branch Brandywine Creek, PA**

*C.V. Shorten, West Chester University / Environmental Health*

Phosphorus is a key nutrient for plant growth but too much of it can trigger unwanted algal growth in waterways. The W. Branch Brandywine Creek in Chester County, PA is plagued by excessive P levels, causing it to fail to meet in-stream water quality standards established by the Clean Water Act of 1972. Phosphorus tends to adhere to solid sediments but evidence suggests that it can be released back to aquatic systems following sediment re-suspension during storm events. This study examines P release kinetics from associated sediments, soils and plant tissue (leaves). Our results from leaching studies for an air-dried, sieved (< 1.0 mm) sediment sample obtained from the site of an old ironworks dam in Hibernia County Park (40.029446°N, 75.835647°W) show that P release follows a two-stage mechanism; fast release occurs over the first few hours of mixing with lab water followed by a slower release mechanism over the next several days. Modeling followed the relationship: Soluble $[PO_4\text{-}P] = C_{Fast}*[1-e^{(-k_{Fast}*t)}] + C_{Slow}*[1-e^{(-K_{Slow}*t)}]$; where C = maximal concentration of fast and slow releases, k = first order rate coefficients for fast and slow release and t = time; model fits showed $C_{Fast} = 0.069$ mg/L, $k_{Fast} = 1.259$ day$^{-1}$, $C_{Slow} = 0.341$ mg/L and $k_{Slow} = 0.002$ day$^{-1}$. Similar results have been obtained for sediments from other creek locations. Sieved (< 1.0 mm) soils from the old ironworks pond basin (now dry; the dam at this site was breached sometime after 1937) were collected at 40, 101, 172 and 203 cm deep, corresponding to different deposition times pre-1940s. These soils failed to show significant P release even after 11 days of mixing. Senescent Sugar Maple (*Acer saccharum*) and American Sycamore (*Platanus occidentalis*) leaves just prior to leaf drop in October were collected, dried at 105°C, crushed and sieved (< 2.0 mm) then added to lab water; mixing for 48 hours showed significant release of P, up to 2.5 mg/L for Maple and 4.7 mg/L for Sycamore after just 24 hours. While these results illustrate P release kinetics from historical sediments and those deposited in the more near term, ongoing work is examining release from fresh, storm-associated sediments. These combined results will help elucidate the mechanisms of phosphorus deposition and transport and can be used to plan for control and cleanup efforts.

**MP128 Monitoring of Endocrine Disrupting Pesticide Residues in Soils in Korea**

*C. Kim, E. Lee, National Institute of Agricultural Sciences, Rural Development Administration; K. Son, National Institute of Agricultural Sciences, Rural Development Administration / Department of Agro-food Safety & Crop Protection; U. Han, National Institute of Agricultural Sciences, Rural Development Administration; H. Lee, Y. Ihm, National Institute of Agricultural Sciences, Rural Development Administration / Department of Agro-food Safety & Crop Protection; S. Hong, National Institute of Agricultural Sciences, Rural Development Administration / Chemical Safety*

To evaluate residues of seventeen pesticides suspected as endocrine disruptor in agro-environment, total four hundred and eighty soils were sampled in nationwide arable land except paddy field on March and April 2000-2002. One hundred and sixty soil samples were collected in green houses cultivated six fruit vegetables (tomato, strawberry, melon, watermelon, cucumber and pepper), leafy perilla and lettuce in 2000. On hundred and seventy soil samples were collected in fields mainly cultivated red pepper, soybean, sesame, perilla, potato, sweet potato and tobacco in 2001. And one hundred and fifty soil samples were collected in orchards cultivated apple, pear, grape, citrus, sweet persimmon and peach in 2002. Carbendazim, mancozeb and vinclozolin as fungicides were detected in two hundred and seventy four, one hundred and sixty three and twelve samples, respectively and their average residue concentrations in positive samples were 0.044 $mgkg^{-1}$ for carbendazim, 0.031 $mgkg^{-1}$ for mancozeb and 0.018 $mgkg^{-1}$ for vinclozolin. Endosulfan, an organochlorine insecticide, was detected in four hundred and forty one samples, and its average residue concentrations in positive samples were 0.25 $mgkg^{-1}$ for greenhouse soils, 0.16 $mgkg^{-1}$ for upland soils and 0.082 $mgkg^{-1}$ for orchard soils. Dicofol, another organochlorine insecticide analyzed, was detected 0.25 $mgkg^{-1}$ of average residue concentration in positive samples in eleven soils. Cypermethrin and fenvalerate as pyrethroid insecticide were detected in four and twelve samples, respectively and their average residue concentrations in positive samples were 0.059 $mgkg^{-1}$ for cypermethrin, 0.013 $mgkg^{-1}$ for fenvalerate. Parathion, an organophosphorus insecticide, was detected in twenty eight samples and its average residue concentration in positive samples was 0.107 $mgkg^{-1}$. Except some outliers such as parathion-applied at near sampling time, average residue concentration was 0.020 $mgkg^{-1}$. Malathion, another organophosphorus insecticide analyzed, was detected 0.006 $mgkg^{-1}$ in one soil samples cultivated garlic. Methomyl, a carbamate insecticide, was also detected 0.066 $mgkg^{-1}$ in one greenhouse soil cultivated lettuce. Carbaryl, another carbamate insecticide analyzed, was not detected at any soil samples. Among four herbicides, alachlor was detected in forty six samples and its average residue concentration in positive samples was 0.041 $mgkg^{-1}$, but metribuzin, and trifluralin were not detected at any soil samples.

**MP129 Background Threshold Values – ProUCL Guidance and Technical Issues (USL, UPL, UTLs)**

*T. Glover, C. Kelly, A. Leiga, P. Chowdhary, Wood Environment & Infrastructure Solutions, Inc*

USEPA's ProUCL statistical package has revolutionized the determination of background threshold values (BTVs) by offering a myriad of options and methods. Unfortunately, guidance on which exact method to use in any particular circumstance is not clearly presented in a single place in the manuals. We will review the types of BTVs available in ProUCL (UTL, UPL, USL), their assumptions and requirements (e.g., no outliers, single population, representativeness, and sample size), and limitations of each type (multiple comparison failure rates, "brittleness" to minor assumption violations, result reproducibility). Also, there will be an overview of how ProUCL can treat non-detect values. A summary table by method including limitations and suggestions will be included based on lessons learned.

**MP130 Applications of NMR Spectroscopy in the Characterization of Contaminated Environments**

*D. Fallaise, University of Guelph / School of Environmental Sciences; J. Konzuk, C. Cheyene, Geosyntec Consultants; E. Mack, DuPont; J. Longstaffe, University of Guelph / School of Environmental Sciences*

Nuclear magnetic resonance spectroscopy is a primary analytical tool for the elucidation of unknown chemical structures, however its application in the area of environmental chemistry is relatively limited. This is particularly true with respect to the practical application of analytical chemistry in the assessment and management of contaminated environments. In general, conventional approaches for environmental analysis are based on the targeted identification and quantification of known or presumed environmental contaminants. This approach is useful for the assessment of most environments relative to regulatory guidelines, however traditional approaches often provide incomplete characterization of environments that are either heavily contaminated or that are contaminated with unknown compounds for which standardized methods have not yet been established. This poster will discuss the application of NMR spectroscopy as a powerful non-targeted analytical tool for the elucidation of unknown contaminants present at heavily contaminated environments. While NMR is not as sensitive as other detection methods, its ability to provide unbiased and unambiguous structural information on unknown constituents can help improve the characterization of the contaminants present at heavily contaminated environments for which conventional analytical tools have been able to provide only partial characterization.

**MP131 Analysis of Artificial Sweeteners by Hydrophilic Interaction Chromatography**

*S. Takemine, M. Motegi, Y. Horii, Center for Environmental Science in Saitama, Japan*

Artificial sweeteners (ASs) including acesulfame (ACE), aspartame (APM), and sucralose (SUC) provide sweetness without adding calories. ASs are widely used as sugar substitutes in foods, drinks, drugs, and sanitary products. Some ASs are excreted unchanged from the human body, and flow down into waste water treatment plants through sewer. ASs having hydrophilic and stable properties are unremoved through waste water treatment, and are discharged into the environment. Recently, environmental occurrence, fate, and ecotoxicological effect of ASs have been investigated in the world. Especially, the two artificial sweeteners ACE and SUC have been found ranged up to 10 µg/L in the water environment. The high aqueous concentrations of ACE and SUC combined with their persistence, high water solubility, and low absorbability to solids also make them virtually ideal anthropogenic wastewater markers. The determination of ASs were usually carried out by solid-phase extraction (SPE) combined with liquid chromatography (LC) /tandem mass spectrometry (MS/MS). However, it was reported that the response of SUC in LC/MS/MS was much lower than those of other ASs. To overcome this problem, in this study, a simultaneous analysis of ASs including SUC by hydrophilic interaction chromatography (HILIC) using a polymer-based column was developed. The target ASs were ACE, APM, SUC, cyclamate (CYC), neotame (NTM), saccharin (SAC). The ASs were analyzed using a polymer-based column (HILICpak VG-50 2D, 150 mm × 2.0 mm i.d., 5 µm particle size; Shodex) and Xevo TQD coupled with ACQUITY UPLC (Waters). The polymer-based column having wide range pH stability is suitable for basic mobile phases. Effects of mobile phase on AS intensity were tested: 0.02 % formic acid, 5 mM ammonium formate, 5 mM ammonium formate (pH 9.5), or 0.1 % ammonium hydroxide as aqueous mobile phase; acetonitrile as organic phase. High-intensity peaks of AS were obtained by the combination of acetonitrile and 0.1 % ammonium hydroxide. The ASs were also good separated by HILIC gradient elution using acetonitrile and 0.1 % ammonium hydroxide solution. Instrumental detection limits ranged from 0.2 ng/mL (ACE) to 0.6 ng/mL (APM). Furthermore, it was confirmed that the HILIC method was applicable to determination of ASs in river water and ground water.

**MP132 Analysis of Volatile and Semi-Volatiles using Thermal Desorption and application to Two Passive-sampling Matrixes**

*R. Scott, Oregon State University / EMT; C. Donald, Oregon State University; P. Hoffman, K.A. Anderson, Oregon State University / Environmental and Molecular Toxicology*

This work describes the development of the thermal desorption extraction process using a Markes Micro-Chamber/Thermal Extractor (M-CTE 250) and the analytical method to examine 35 volatile organic compounds (VOCs) including BTEX and alkanes, 6 Tri-alkyl/phenyl-organophosphates (Tri-R's), 8 oxygenated polycyclic aromatic hydrocarbons (OPAHs), and 28 polycyclic aromatic hydrocarbons (PAHs). This methodology dramatically reduces the use of organic solvent and preforms this analysis in a single quantitative run using a Markes thermal desorption system interfaced with an Agilent 6890N gas chromatograph / 5975B mass spectrometer (GC/MS). Volatile organic compounds had an average detection limit (DL) of 1.0ng, Tri-R-phosphates had a DL of 3.0ng, OPAH's had a DL of 1.5ng, and PAHs had a DL of 1.1ng with a run time of 31.13mins. Analytic method validation included standard spiked wristband passive samplers and artificial turf analyzed in replicates of three on three different days. VOCs had an average recovery of 89.3% and 5.1% relative standard deviation (RSD), Tri-Rs had a 105.1% recovery with a 13.7% RSD, OPAHs 65.5% recovery with a 9.3% RSD, and PAHs a 94.1% recovery and a 7.2% RSD.

**MP133 PFAS analysis in surface water using Agilent Ultivo triple quadrupole LC/MS with ASTM D7979 with the addition of Gen-X and Adona**

*E. Parry, Agilent Technologies; T. Anumol, Agilent*

Per/Polyfluoroalkyl substances (PFAS) are chemicals found in firefighting foams in consumer products requiring water resistant and stain repellant properties. The USEPA has made addressing PFAS water contamination a national priority, due to their presence in US drinking water sources. EPA method 537, specific to drinking water, provides a direct injection method for 14 PFAS compounds. For other types of water samples, ASTM D7979 provides a simple extraction and analytical method for 21 PFAS compounds. Currently, new fluorochemicals such as GenX and Adona are being identified in the environment and classified as problematic. The Agilent Ultivo is a stackable triple quadrupole liquid chromatogram mass spectrometer (LC/MS). We demonstrate the robust analytical performance of Gen X, Adona, and ASTM D7979 targets in surface water. Minimal method modification was required to accommodate the additional analytes.

**MP134 Contamination Analysis of the NIST Marine ESB's Post-Homogenization Cleaning Protocols**

*J. Trevillian, National Institute of Standards & Technology / Chemical Sciences Division; D. Ellisor, National Institute of Standards and Technology; K. Huncik, National Institute of Standards and Technology / Chemical Sciences Division; W.C. Davis, National Institute of Standards and Technology / Chemical Sciences Division/ Hollings Marine Laboratory; J. Ragland, A. Moors, National Institute of Standards and Technology; R. Pugh, National Institute of Standards and Technology / Chemical Sciences Division*

The National Institute of Standards and Technology's (NIST) Marine Environmental Specimen Bank (Marine ESB) provides researchers with homogenized tissues to be analyzed for a variety of biological and chemical indices. Tissues are cryohomogenized using polytetrafluoroethylene (PTFE) disk mills specifically designed for the process and tissue homogenates are aliquoted into perfluoroalkoxy alkane (PFA) jars. While the PFA jars come cleaned directly from the manufacturer and have not previously come into contact with biological tissues, the PTFE disk mills are custom made and expensive so consequently are reused. Therefore, after cryohomogenization is complete, dirty disk mills are washed according to Marine ESB protocols. Although this has been standard practice since the inception of the Marine ESB, little was known about potential carry-over of contaminants from sample to sample via cleaned and reused PTFE disk mills. Therefore, an investigation was conducted to evaluate the effectiveness of eliminating compounds commonly assessed in Marine ESB samples (i.e., organic and inorganic analytes) using the established cleaning protocol. Long-finned pilot whale (*Globicephala melas*) blubber and pygmy sperm whale (*Kogia breviceps*) liver samples were cryohomogenized and aliquoted into pre-cleaned PFA jars. The used PTFE disk mills were cleaned according to Marine ESB protocols. Once dry, the PTFE disk mills were rinsed three times with analysis-appropriate solvents in order to extract any remaining analytes, which could result in carry-over contamination. Homogenates and disk mill rinsates were analyzed in NIST's Analytical Chemistry Labs. Organic analytes (i.e., polychlorinated biphenyls (PCB) and organochlorine contaminants (OC)) were analyzed using gas chromatography-mass spectrometry (GC/MS). Inorganic analytes (i.e., trace elements) were analyzed using inductively coupled plasma mass spectrometry (ICP-MS). Results from this study indicate the cleaning protocol established by the Marine ESB sufficiently removes organic and inorganic analytes from used equipment with minimal carry-over between samples as a result of the post-homogenization cleaning procedure.

**MP135 Novel in vivo sampling probe based on water-absorption for ultrasensitive neonicotinoids determination in vegetable**

*J. Qiu, J. Gan, University of California, Riverside / Environmental Science*

Neonicotinoids represent the fastest growing class of pesticides, of which imidacloprid is the most used worldwide. However, due to the unique physical-chemical properties of neonicotinoids, sampling, especially in vivo sampling in plant tissues, represents a formidable challenging. In this study, we developed a functionalized solid-phase microextraction (SPME) probe with a strong capability for water absorption and tested it for direct in vivo sampling of neonicotinoids in vegetable tissues. The coating of the SPME probe possessed both water absorption and bioinspired antibiofouling properties. After sampling, the SPME fiber was retrieved, freeze-dried, and directly desorbed into a UPLC-MS/MS system for quantification. The coating was demonstrated to be much more superior to the commercial SPME fiber coatings. The method showed outstanding extraction capacity and efficiency toward neonicotinoids, and high sensitivity as well as reproducibility , suggesting a great applicability for in vivo application in live plants. This novel sampling technique opens up new avenues for the facile and efficient in vivo sampling of neonicotinoids in plant tissues and may be used to improve our understanding of ecotoxicological effects of this important class of insecticides, including their deleterious effects on pollinators.

**MP136 Method for the Determination of Drugs and Pesticides in Catfish Feed for Contaminant Traceback**

*S. Boone, J. Atkins, M. Green, Mississippi State Chemical Laboratory; A. Meredith, Mississippi State Chemical Laboratory / Mississippi State University / Department of Biochemistry, Molecular Biology, Entomology and Plant Pathology; C. Childers, Mississippi State Chemical Laboratory; D. Sparks, Mississippi State Chemical Laboratory / Biochemistry, Molecular Biology, Entomology, & Plant Pathology; G. Hagood, Mississippi State Chemical Laboratory; A. Brown, Mississippi State Chemical Laboratory / Mississippi State University / Department of Biochemistry, Molecular Biology, Entomology and Plant Pathology*

To ensure the safety of the food supply in the US, many organizations are working to develop and improve testing methods. In cooperation with the USDA/FSIS/FERN, the Mississippi State Chemical Laboratory (MSCL) has developed a method for the determination of drugs and poisons in catfish feed using GC/MS/MS and LC/MS/MS analysis. A surveillance program within the state supports the growth of the catfish industry in Mississippi and is based upon generating a product that tastes good and is safe for all consumers. The MSCL analyzes multiple compounds (currently-used pesticides and metabolites) in farm-raised catfish, and participates in TOX 1 screening of catfish for the USDA/FSIS/FERN. The feed method analytes include: acephate, aldrin, arecoline, atrazine, azoxystrobin, bifenthrin, chlorpyrifos, clomazone, chloransulam-methyl, codeine, cyfluthrin, cyhalothrin, cypermethrin, DDE, DDT, deltamethrin, diazinon, dicofol, dicrotophos, diuron and metabolites (DCPMU, DCPU), endrin, fentanyl, fenvalerate, flonicamid, flumetsulam, formesafen, imidacloprid, malathion, myclobutanil, nicotine, paraxoon, parathion, pentazocine, phorate, pilocarpine, profenofos, propiconazole, pyraclostrobin, scopolamine, strychnine, terbuphos, tetramine, thiamethoxam, and tribufos. An Agilent 7890A/7000 Triple Quad MS equipped with a HP5MS and an Agilent 1290 LC/6460 Triple Quad MS equipped to an Eclipse Plus C18 are used for the analysis of the compounds. The method includes extraction of fish feed in water (two shakes, one basic and one acidic), acetonitrile, and QuEChERs packet (AOAC), followed by centrifugation. The extracts have various matrix effects depending upon the type of feed. The addition of an alumina SPE column coupled to a C18 SPE column decreases the matrix effects while maintaining acceptable recovery rates for most compounds in a screening method. The columns are eluted with 0.1% formic acid in acetonitrile. Recovery of most compounds are greater than 60%, except pentazocine – 53%, scopolamine – 56%, strychnine – 40%, codeine – 36%, arecoline – 33%, and nicotine – 0%. The drug and pesticide catfish feed method has added an additional tool to the laboratory to help to identify contaminants in catfish feeds that may adulterate the edible catfish fillets when fed to fish. This method will increase the capacity of USDA's surveillance sampling and provide the ability to test a potential source of contamination.

**MP137 Urinary biomarker discovery of toxicants using mass spectrometry-based metabolomics data processing approaches**

*C. Shih, J. Hsu, L. Ma, P. Liao, National Cheng Kung University*

Toxicant metabolites are taken as biomarkers for human toxicant exposure assessments. Metabolism within an organism is extremely complex. To detect toxicant metabolites from such a complex matrix is challenging. Mass spectrometry-based metabolomics data processing approaches have emerged as an ideal method of exposure marker identification. Ultra-performance liquid chromatography coupled with Orbitrap high-resolution mass spectrometry (MS) and two data processing approaches, the signal mining algorithm with isotope tracing (SMAIT) and the mass defect filter (MDF), were used for toxicant exposure biomarker discovery. Di-(2-propylheptyl) phthalate (DPHP) was taken an example toxicant. DPHP is a plasticizer used in polyvinyl chloride and vinyl chloride copolymer that has been suggested to be a toxicant in rats and may affect human health. Because the use of DPHP is increasing, the general German population is being exposed to DPHP. To date, the knowledge regarding DPHP metabolism has been limited, and only four metabolites have been validated in human urine. Our results show 13 and 104 metabolite candidates were identified by the MDF and SMAIT, respectively, in in vitro DPHP incubation samples. Of these candidates, 17 were validated as tentative exposure biomarkers using a rat model, 13 of which have not been previously reported. The two approaches generated rather different DPHP exposure biomarkers, indicating that these approaches are complementary for discovering exposure biomarkers. Compared with the four previously reported DPHP metabolites, the three novel biomarkers had higher peak abundances, and two of them were confirmed as DPHP structure-related metabolites based on their MS/MS product ion profiles. The mass spectrometry-based metabolomics data processing approaches were successfully applied to identify toxicant exposure biomarkers.

**MP138 Development of a multi-mycotoxin analysis method in wine by LC-MS/MS featuring a comparative extraction study**

*M. Annunziato, J. Berry, Florida International University / Chemistry*

Studies concerning the contamination of Wine by mycotoxins such as Ochratoxin A and the Fumonisins during the process of producing wine have been widely documented. Fusarium mycotoxins and Aflatoxin are not usually detected or reported in wine, however this is not confirmation that they do not contaminate wines as various factors including climate change have increased concern for the contamination of wine by these mycotoxins. Methods that do include multi-mycotoxin analysis, usually employ classical extraction techniques such as liquid–liquid extraction (LLE) or solid–phase extraction (SPE), which include several disadvantages such as large sample volumes, extensive amounts of hazardous solvents, and time-consuming sample preparation. This study compared a variety of extraction methods aimed at lowering sample extraction time, decreasing cost, and lowering solvent/sample usage while retaining simplicity. A salting-out liquid–liquid extraction (SALLE), modified QuEChERS (quick, easy, cheap, effective, rugged, and safe) method, and Dispersive liquid–liquid microextraction (DLLME) method where employed for the quantitative analysis of 14 different mycotoxins (Zearalenone, Ochratoxin A, Patulin, Deoxynivalenol, Nivalenol, AFB1, AFG1, FB1, FB2, Tenuazonic Acid, Alternariol, Citrinin, T-2, HT-2) by LC-MS/MS to determine the occurrence of these toxins in imported and domestic wine samples.

**MP139 Method Validation for the Determination of Herbicide "X" in Larval and Adult Bee Diet**

*T. Paz, L. Zhang, K. Keller, K. Martin, EAG Laboratories*

The honey bee *(Apis mellifera)* is an important pollinator for a variety of agricultural crops. Its importance in agricultural success has caused investigators to use the honey bee as a test species for the evaluation of the effects of agricultural chemicals on non-target insects. This is in accordance with the guidelines set by the Environmental Protection Agency (EPA) for the registration of chemical substances whose regulations require a risk assessment on the potential harm of chemical substances to humans, wildlife, and non-target organisms. In order to support the toxicity test of herbicide "X" on the honey bee, an analytical method was developed and validated to determine the amount of herbicide "X" in larval diet and adult bee diet (sugar water), the diet being the means of exposure to the honey bee. Larval diet samples were prepared using appropriate stock solutions in acetone. Due to poor recoveries the solubility of herbicide "X" in sugar water was investigated through a series of trials in order to determine the most effective method of introducing herbicide "X" to the matrix. The composition of the sugar water (50% versus 67% sugar water) and fortification method (fortification using stock solution versus formulation) was investigated. The method yielding the highest percent recoveries used 67% sugar water and fortification with formulation of herbicide "X". The method was validated through a series of matrix blanks and fortifications. The matrix fortification for the larval diet was performed in quintuplicate at 40.9 and 1636 mg a.i./L and the sugar water performed in quintuplicate at 300 and 4500 mg a.i./kg. Samples were processed through a series of dilutions which included matrix matching. Matrix fortifications were analyzed against standards prepared from the reference substance also made in matrix matched solution. Matrix fortifications were analyzed using HPLC with ultraviolet detection. The compound's percent recovery was calculated using a combination of OpenLab and Microsoft Excel 2010. Mean percent recovery at the low concentration level for larval diet was 96.8% and the high level was 86.7% with an overall precision of 6.65%RSD. Mean percent recovery at the low concentration level for sugar water was 114% and the high level was 114% with an overall precision of 7.54%RSD. Validation results suggest herbicide "X" in larval diet and sugar water can be accurately determined using the analytical method.

**MP140 Simultaneous determination of neurotransmitters and their precursors /metabolites in animal brain tissue**

*Y. Nojima, R. Tanoue, T. Kunisue, S. Tanabe, K. Nomiyama, Ehime University / Center for Marine Environmental Studies*

Endogenous neurotransmitters play a critical role in function of central nervous system (e.g., activity, attention, emotion). Some in vivo studies have been reported alterations in the brain levels of several neurotransmitters following exposure to environmental pollutants such as polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs). However, the mechanisms of neuroendocrine disruption are still unclear, and there has been an increasing demand for quantification of neurotransmitters and their precursors/metabolites in biological matrices. The present study aimed to develop an analytical method for 14 neurochemicals of not only neurotransmitters but also precursors and metabolites in animal brain tissues by using ultra-fast liquid chromatography-tandem mass spectrometry (UFLC–MS/MS). Protein precipitation with acetonitrile was chosen for cleanup because the process reduced signal suppression for target compounds, and thus, protein precipitation. To evaluate extraction efficiency and recovery, 3 different types of extraction solvents, which were methanol/Milli-Q water (1:1, v/v) (1) non-acidified, (2) acidified with acetic acid and (3) acidified with formic acid, were tested. When using the solvent acidified with formic acid, the highest extraction efficiency was observed for dopamine, L-Dopa and 3-MT. On the other hand, low recovery rates of norepinephrine and octopamine were found. Thus, the solvent acidified with formic acid was adopted for analysis of dopamine, L-Dopa and 3-MT, while non-acidified solvent was used for extraction of the other compounds. In this analytical condition, acceptable recovery rates (71%–120%) and intra- and inter-day precision (CV: < 7% and < 10%, respectively) were obtained. The limits of quantification, which were estimated as the concentrations giving a peak with a signal-to-noise ratio of 10 in brain extracts, ranged from 3.4 to 330 ng g-1 wet weight for the target neurochemicals. These values were comparable to or lower than those reported in previous studies. The developed method was finally applied to brain tissues of 3 beagle dogs, and 4 neurotransmitters and 4 precursors/metabolites were successfully quantified. Our UFLC–MS/MS method allows the exploration of the profile changes of neurotransmitters caused by exposure to environmental contaminants such as PCBs and PBDEs.

**MP141 Nanosecond pulsed electric field incorporation technique to predict toxicity of equine estrogens on medaka embryos**

*K. Arizono, Pref. Univ. Kumamoto / Faculty of Env Symbiotic Science; M. Uchida, Ariake National College of Technology / Department of Creative Engineering; H. Ishibashi, Ehime University / Faculty of Agriculture; S. Fukushima, Prefectural University of Kumamoto / Faculty of Env Symbiotic Science; N. Tominaga, Ariake National College of Technology / Department of Creative Engineering*

Using a nanosecond pulsed electric field (nsPEF) technique, we have assessed teratogenicity and embryonic developmental toxicity of equine estrogens (Eqs) and also tried to predict the molecular mechanisms of teratogenicity and embryonic developmental defects caused by Eqs on medaka (Oryzias latipes). The 4-5-h post-fertilization embryos were exposed to co-treatment with 0.1, 1, 10 ppm Eqs (equilin:Eq and equilenin:Eqn ) and nsPEF and then continuously cultured until hatching. Results documented that the time to hatching of embryos which exposed with 1ppm of both Eq and Eqn by nsPEF groups was significantly delayed in comparison to the control group. In addition, an abnormal embryo development such as the severe dysfunction, the delay of blood vessel formation and teratogenicity (abnormal bone formation) was observed in the surviving medaka eggs from 10 ppm of both Eq and Eqn exposure using nsPEF. The nsPEF incorporation technique can import Eqs within very narrow time windows in the early embryonic stages. From the results in this study, we indicated that our nsPEF technique become a powerful tool for assessing teratogenicity and embryonic developmental toxicity of chemicals, and also enable to predict their molecular mechanisms in medaka embryos.

**MP142 Novel High Through-Put Screening of Transition Metal-Based Anticancer Compounds Using Zebrafish Embryo Larval Assay and ICPMS Analysis**

*B. Karas, Rutgers University / Toxicology; L. Côrte-Real, A. Valente, Faculdade de Ciências da Universidade de Lisboa / Centro de Química Estrutural; K.R. Cooper, B. Buckley, Rutgers University / Environmental and Occupational Health Science Institute; L.A. White, Rutgers University / Department of Biochemistry and Microbiology*

The use of the zebrafish embryo larval assay (ZELA) as a whole organism high throughput screening method for potential anticancer drug candidates coupled with ICPMS has proven to be a valuable research tool. This bioanalytical assessment of delivered tissue doses allows for expedited screening of potency and idiopathic off-target effects. Additionally, the zebrafish model allows for examining adverse outcome pathways from biochemical to whole organism endpoints, which are difficult to do in cell culture and cost limiting using rodent models. ZELA is especially relevant to the success and prolific development of metal-based compounds. The ability to screen large numbers of these anticancer compounds makes ZELA desirable. We hypothesize that the zebrafish model coupled with ICPMS could be used to evaluate potency, off-target toxicity, efficacy, and tissue dose. As an initial proof of principle toxicity studies using cisplatin were carried out. An embryo digestion and ICPMS method was developed for the detection of Pt and was found that for following waterborne exposure concentrations of 0, 3.75, 7.5, 15, 30 and 60 mg/L, the respective doses were 0.05, 8.7, 23.5, 59.9, 193.2, and 461.9 ng of Pt per embryo (Pt/E). Dose response curves for lethality and a non-lethal delayed hatching endpoint were calculated. The lethal endpoints were determined: LC50: 31 mg/L for waterborne exposure, LD50: 193.2 Pt/E for quantified delivered dose. For the delayed hatching endpoint, the LOAEL for waterborne exposure was 3.75 mg/L and an associated delivered dose of 8.7 Pt/E; and an EC50 of 4.6 mg/L. A proprietary Ru-based molecule, LCR134, was also evaluated and resulted in an LC50 of 4.4 µM, EC50 of 3.5 µM, NOAEL of 2 µM and lethal tissue dose of 3 significant differences in total body length, intraocular distance, pericardial and yolk sac size were observed. Additionally, several organ systems had lesions and the underlying mechanisms will be examined to better understand potential side effects that may be observed in rodent or human drug trials. This research was funded by NJAES-Rutgers NJ01201, NIH-MIEHS P30 ES005022, and Training Grant T32-ES 007148, FCT (project UID/QUI/00100/2013), Valente, A. acknowledges the Investigator FCT2013 Initiative for the project IF/01302/2013 (acknowledging FCT, as well as POPH and FSE – European Social Fund). Côrte-Real, L. thanks FCT for her Ph.D. Grant (SFRH/BD/100515/2014).

**MP143 Uptake and sublethal toxicity of nanogold (nAu) in the nematode *Caenorhabditis elegans***

*S. Bosch, North-West University / School of Biological Sciences / Environmental Sciences; T. Botha, North-West University / School of Biological Science; M. Maboeta, V. Wepener, North-West University / Unit for Environmental Science and Management*

The nematode *Caenorhabditis elegans* is used as an ecotoxicological model species in both aqueous medium and in solid substrates. It is easy and low-cost to maintain in the laboratory and it produces hundreds of offspring within a short period of time. It also has a small body size (1 mm), making it possible for in vivo assays to be conducted in 12-well plates. Engineered nanomaterials (ENMs) are a class of emerging pollutants. Nanogold (nAu), is used in many consumer products and in vivo drug delivery. These materials can be released in to the aquatic environment during production or discarding of consumer products. As nAu is insoluble in water, the sediment would become the final depository for the materials. It has become increasingly important to use sediment dwelling organisms to screen for possible toxicity of these ENMs. In this study *C. elegans* was exposed to a range of concentrations of nAu and ionic gold in M9-media, acting as a substitute for pore water. After 96 hours growth, fertility and reproduction was determined. Ultrastructure damage and internalisation of particles in *C. elegans* was determined by using TEM and CytoViva hyperspectral imaging. From these images the nanomaterials are distributed within the reproductive organs, as well as the intestine. Results obtained indicate that nAu affects reproduction more than growth, albeit at very high exposure concentrations, indicating no toxicity at environmentally relevant concentrations. These results give more information regarding the toxicity and in vivo uptake of nAu and form part of an environmental risk assessment of ENMs.

**MP144 Parabens and their metabolites in pet food and urine from New York State, USA**

*R. Karthikraj, S. Borkar, S. Lee, NYSDOH / Wadsworth Center; K. Kannan, Wadsworth Center / New York State Department of Health / Division of Environmental Health Sciences*

In recent years, there is a growing concern on pet animals' health as they are exposing to several chemicals in indoor environment, as like humans. Hence, pets can serve as a sentinel to human exposure. In this study, we determined the concentrations of parabens and their metabolites in commercially available cat ($n$ = 35) and dog foods ($n$ = 23) as well as in urine samples (cat, n = 30; and dog, n = 30) collected from the Albany area of New York State, United States. Mean concentrations of total parabens (i.e., sum of parabens and their metabolites) in dog and cat food were 1350 ng/g and 1550 ng/g fresh wt, respectively and in dog and cat urine were 7230 ng/mL and 1040 ng/mL, respectively. The detected concentrations of parabens and their metabolites indry food were higher than that found in wet food. Similarly, cat food contained higher concentrations of target chemicals than the dog food. In both pet food and urine, methyl paraben (among parabens) and 4-hydroxy benzoic acid (among metabolites) were predominantly found. We estimated the daily dietary intake (EDI) and cumulative daily intake (CDI) and found that there are other possible sources for paraben exposures to the dogs, whereas, for cats, diet is the most of exposure source.

**MP145 Urinary concentrations of phthalate metabolites in pet cats and dogs: A comparison and risk assessment study**

*R. Karthikraj, S. Lee, NYSDOH / Wadsworth Center; K. Kannan, Wadsworth Center, New York State Department of Health / Division of Environmental Health Sciences*

In recent years, there is a serious concern on raising health issues in pet animals due to their wide exposure to environmental chemicals that are present in indoor, food and other consumer products. Phthalates (diesters of phthalic acid) are one such group of chemicals have been widely used in several commercial and consumer products as plasticizers, solvents/additives and flame retardants. However, they are linked to several health outcomes in human due to their endocrine disrupting activities. To the best of our knowledge, studies on pet animal's exposure to phthalates are scarce. Hence in the present study, we determined the concentrations of 22 metabolites of phthalates (PhMs) in pet cats (n = 50) and dogs (n = 50) urine collected from New York State, USA. The total PhMs concentration in cats was ranged between 64 to 6500 ng/mL, whereas in dogs it was 13 to 3300 ng/mL. The median concentration of total PhMs was ~5 folds higher in cats (600 ng/mL) than in dogs (128 ng/mL). Overall, 9 PhMs were consistently found in all the studied cats and dogs urine (*df %* 100). PA (non-specific metabolite) was the highest abundant chemical in both cats and dogs. We did not find any significant difference in concentration profiles between age groups and sex ($p > 0.05$) among the studied set of samples. Based on the estimated daily intakes (EDI) and Hazardous quotient (HQ) values, cats were at higher risk than dogs due to the expose to phthalates.

**MP146 Acute Toxicity of Corexit 9500A and Assessment of Dioctyl Sulfosuccinate for Monitoring Four Oil Spill Dispersants Applied to Diluted Bitumen**

*C. MacInnis, P. Brunswick, G. Park, Environment and Climate Change Canada / Pacific and Yukon Laboratory for Environmental Testing; C. Buday, Environment and Climate Change Canada / Pacific Environmental Science Centre; G. Schroeder, B. Fieldhouse, C. Brown, G.C. van Aggelen, D. Shang, Environment and Climate Change Canada / Pacific and Yukon Laboratory for Environmental Testing*

Oil dispersants are complex mixtures of solvents and surfactants used to reduce the surface tension of oil slicks through amphipathic surfactant interactions. By encouraging oil droplets to move into the water column from the surface, dispersants minimize surface water contamination and aim to reduce the impact of a spill on coastal wildlife. Future diluted bitumen (dilbit) transportation projects in British Columbia are forecasted to increase coastal tanker traffic, making it important to consider effective oil spill remediation techniques. This study investigated the acute toxicity of the oil dispersant Corexit EC9500A in fish species relevant to the British Columbia coast and assessed the suitability of the commonly used oil dispersant indicator, dioctyl sulfosuccinate (DOSS), in the presence and absence of dilbit. Corexit EC9500A 96-h median lethal concentration (LC50) bioassays were conducted for the freshwater species rainbow trout and seawater species coho, chinook, and chum following standard Environment and Climate Change Canada reference testing method. The final LC50 values for tested seawater species ranged between 35.3 and 59.8 mg/L. Variability in DOSS recovery throughout LC50 testing prompted an investigation of DOSS as an indicator for four DOSS containing oil dispersants Corexit EC9500A, Finasol OSR52, Slickgone NS, and Slickgone EW. For up to 13 days at 5°C and 8 d at 10°C, the DOSS indicator was found to be stable. At temperatures ≥15°C, however, the DOSS indicator was found to be stable for only 3 d, after which DOSS recovery became variable and dependent on environmental factors such as temperature, microbial activity, and aeration. From this study, it was concluded that DOSS is a discrepant indicator and may not accurately correspond to other dispersant components after its application to seawater oil spills.

**MP147 Contaminant mixtures and predicted effects in wadeable streams of the southeastern United**

*P.M. Bradley, C. Journey, USGS / South Atlantic Water Science Center*

Complex contaminant mixtures and associated aquatic-health effects are growing concerns. Replicate (n = 3-10) water samples were collected from 54 small Piedmont (USA) streams over 10 weeks in 2014 and analyzed for 489 organic analytes (470 unique chemicals), including 110 pharmaceuticals and degradates, 226 pesticides and degradates, 84 volatile organic chemicals, and 69 organic waste indicator compounds. Of these, 264 (56%) were detected at least once across all sites. Approximately 70% of the detected water contaminants were designed-bioactive organic chemicals (e.g., pharmaceuticals, pesticides). Due to multiple modes of action, high bioactivity, biorecalcitrance, and direct environment application (pesticides), frequent detection of designed-bioactive organics (range up to more than 100; median greater than 40 per site) at cumulative concentrations up to $\mu g\ L^{-1}$ raise concerns for sub-lethal effects to sensitive aquatic species and lifecycle stages. The possible effects of the complex chemical exposures observed in this study were computationally predicted using knowledgebase-leveraging tools.

**MP148 Determination of the Biosorption Capacity and Biochemical Response of *Chlorella vulgaris* Upon Exposure to Elevated Manganese Concentrations**

*N. Perry, A.L. Smythers, Marshall University; A.G. Pauley, D.R. Kolling, Marshall University / Department of Chemistry*

Manganese is introduced into water sources by mine runoff, fracking, and industrial waste processes. Overexposure to Mn leads to a variety of health issues in humans, including progressive, irreversible neurodegenerative effects, increased heart rate and blood pressure, liver damage, decreased fertility, and increased fetal abnormalities. A possible remedy of this problem may be found in algae, which has been used to remove contaminants such as phosphates and nitrates from water sources in previous research. Ideally, the algae could then be harvested to produce value added products, such as triaclyglycerols for use in biodiesel production. *Chlorella vulgaris* is a unicellular green microalga that can produce up to 41 % lipids per dry mass with a short doubling rate, making it an ideal biofuel feedstock. While it has the ability absorb heavy metals, high concentrations may prove toxic, reducing the bioaccumulation ability. In studies of Cd, Cu, and Zn, *C. vulgaris* experienced metal toxicity with symptoms including reduced cell growth, decreased pigment concentrations, and decreased production of proteins and carbohydrates. The objective of this study was to determine to what extent and the mechanism for how Mn bioaccumulates in *C. vulgaris* and how increased Mn concentrations affect the biochemical composition of the alga. This information could be used to determine if the alga is a viable organism to use for bioremediation. Furthermore, if the biochemical processes are not negatively affected, it could be harvested to produce biofuels after cleaning up the polluted waters. The goal of this experiment was accomplished by growing the algae in medium with increased Mn concentrations, assaying for the changes in metabolic processes, and then determining the intracellular and extracellular Mn concentrations via inductively coupled plasma optical emission spectroscopy. The cultures were also monitored for lipid synthesis efficiency, pigment accumulation, photosynthetic efficiency, carbohydrate production, and cell mass. Preliminary results indicate that *C. vulgaris* has the capacity to bioaccumulate up to 1.25 mg/mL of Mn while showing a maximum of a 25% reduction in terminal turbidity. Additionally, the algae grown in increased Mn concentrations take longer to reach maximum photosynthetic efficiency, but maintain the peak photosynthetic efficiency for a greater amount of time. As a result, we expect the cells will produce more carbohydrates and lipids.

**MP149 Temporal and Spatial Trends of Organochlorine Compounds in Herring Gull (*Larus argentatus*) Eggs from the Great Lakes in Michigan, USA, 2002-2017**

*M.E. Barton, University of Maryland / Environmental Science and Technology; K.G. Drouillard, University of Windsor / Great Lakes Institute for Environmental Research; K.D. Hughes; S. de Solla, Environment Canada / Ecotoxicology and Wildlife Health Division; W.W. Bowerman, University of Maryland / Environmental Science & Technology*

The Clean Michigan Initiative-Clean Water Fund has supported a 15-year-long biomonitoring program of several organochlorine (OC) contaminants in herring gull (*Larus argentatus*) eggs from Lake Erie, Lake Huron, Lake Michigan, Lake Superior, and the St. Mary's River in Michigan from 2002-2006 and 2008-2017. This monitoring study provides a dataset from the United States that mirrors the Environment and Climate Change Canada's (ECCC) Great Lakes Herring Gull Contaminant Monitoring Program dataset. These contaminants include polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), and several organochlorine pesticides such as dichlorodiphenyltrichloroethane (DDT) and its ubiquitous metabolite dichlorodiphenyldichloroethylene (DDE). 77 compounds in total were analyzed, as well as 60 TEQs calculated for individual PCBs, PCDDs, and PCDFs. Every year, thirteen eggs were randomly selected from each colony (two colonies per Lake/River, one egg per nest) and analyzed via gas chromatography (GC) at the Great Lakes Institute for Environmental Research, using a similar protocol used by ECCC. Eggs were either analyzed individually or as composites and spatial and temporal trends were assessed for burdens in eggs. Additionally, a Wildlife Contamination Index (WCI) was calculated using several legacy compounds including organochlorines, PCDDs, and PCDFs to assess risk to piscivorous wildlife, rank colonies based on exceedances of guidelines and assess temporal changes in exceedances of guidelines at individual colonies. Calculation of WCIs is ongoing. It is hypothesized that this metric will correlate to either TEQs for each class of compound or the chemical concentrations in the eggs as assessed by GC. General trends in concentrations over this period of time reveal that Lake Erie is ranked the most contaminated for ΣPCBs, octachlorostyrene, dieldrin, *α*-Chlordane, *p,p'*-DDT, and *p,p'*-DDD. Lake Superior is ranked the most contaminated for *β*-Hexachlorocyclohexane, *oxy*-Chlordane, and *cis*-Nonachlor. These and other values in some cases exceed the NOAELs or LOAELs for double-crested cormorants (*Phalacrocorax auritus*), which stand in for toxicity reference values for herring gulls. These data taken together demonstrate that the Great Lakes still carry a relatively high burden of legacy contaminants that may be affecting the health of avian populations.

**MP150 Site-Specific Bioaccumulation Study of Dioxin/Furan Uptake at a Wetland: Consequences to Decision-Making**

*M. Shibata, ERM, Inc. / Risk Services; G.C. Weber, ERM*

Polychlorinated dibenzo-dioxins/furans (PCDDs/PCDFs) are substances of great concern because of their persistence, ability to accumulate in organisms, and high toxicity. PCDDs/PCDFs are a co-contaminant of wood treatment processes and were historically released into an adjacent freshwater seasonal wetland. In addition to providing economic and social benefits, wetlands are among the most productive ecosystems and frequently provide important habitat and food sources for many resident, migratory, and protected wildlife. A bioaccumulation study was conducted to assess site-specific foodchain exposures to PCDDs/PCDFs by wildlife and re-galvanize a stalled Feasibility Study process. In support of scoping a remedy, site-specific uptake rates were then used to derive risk-based target levels that are protective of the site's wetland. A statistically defensible sampling design was negotiated and implemented – data were deemed of sufficient quality to derive site-specific uptake rates. As hypothesized, this study suggested that uptake into wetland invertebrates were well below values published in the scientific literature. A sensitivity analysis was conducted and demonstrated that moisture content of sediments and invertebrate tissue that are typically accounted for through ingestion or uptake rates can have a notable influence on risk-based cleanup targets. Consistent with the overall aim to avoid 'destroying the wetland in order to protect it', these defensible low uptake rates resulted in risk-based cleanup targets that were protective and yet supported limited intrusive and potentially destructive remediation efforts heretofore considered for the seasonal wetland. Comparable cleanup targets were verified by the oversight regulatory agency. Benefits included: [i] a streamlined agreement on the scope and proposed remedy options and [ii] protective, cost-effective remedial actions.

**MP151 ChemTHEATRE, a platform to browse the published or public data of environmental monitoring and its use for risk assessment**

*K. Nakayama, Ehime University / Center for Marine Environmental Studies; B. Lin, National Institute of Advanced Industrial Science / Research Institute of Science for Safety and Sustaintability; T. Isobe, National Institute for Environmental Studies / Center for Environmental Health Sciences; S. Uno, Kagoshima University / Faculty of Fisheries; I.C. Handoh, Niigata University / Graduate School of Science and Technology; N. Ohno, University of Hyogo / Graduate School of Simulation Studies; T. Kunisue, Ehime University / Center for Marine Environmental Studies*

There is a general trend toward the growing importance of open data worldwide. It appears to be essential that development of scientific data repositories be accelerated. In the field of environmental chemistry and ecotoxicology, a huge number of monitoring data on chemicals in various environmental and biological specimens have been reported in scientific journals. However, comprehensive, public repositories to store such valuable data set of the chemicals do not exist; researchers are forced to spend lots of time and cost in collecting and utilizing the published data, when modelling environmental behavior and fate of, and performing the risk assessment for, the chemicals of interest. Therefore, it is desirable that various stakeholders in the field should work together to improve and promote secondary use of the data. To this end, we have created a platform to register and visualize the monitoring data of environmental contaminants, named 'ChemTHEATRE' (Chemicals in the THEATRE: Tractable and Heuristic E-Archive for Traceability and Responsible-care Engagement). To date, data described in more than 66 projects have been registered on the platform. Users can find e-archived chemical concentration data in the environmental and biological specimens each with associated metadata such as sampling date and location, species, and biometrics, in addition to the detailed description of experimental methods. Bridging ChemTHEATRE to AIST-MeRAM (Multi-purpose Ecological Risk Assessment and Management Tool) storing chemical property and/or hazard/toxicity information provides us high accurate and transparent assessment of ecological risk of chemicals. Much effort is currently being devoted to visualizing e-archived data sets, and enhancing available data-model interfaces to simulate global dynamics of chemical pollution, with Finely-Advanced Transboundary Environmental model (FATE), and to promote a series of integrated exposure and effects analyses. It is thus expected that ChemTHEATRE will be not only a dedicated follow-up and forecasting tool of international regulations on pollution control in the light of traceability and responsible-care engagement of chemicals, but also a 'communication theatre' where a variety of stakeholders can improve their risk literacies and develop new projects through open data access.

**MP152 Elucidating the Effects of Arsenic and Estrogen on Wound Healing**

*B.I. Pinto, Northern Arizona University / Center for Bioengineering Innovation; O. Lujan, T. Bardsley, Northern Arizona University / Biology; C. Propper, Northern Arizona University / Biological Sciences; R.S. Kellar, Northern Arizona University / Center for Bioengineering Innovation*

Arsenic is a naturally occurring environmental contaminant that is harmful to humans at elevated concentrations. Increased levels of arsenic in the environment occur as a result of human activities (anthropogenic) and from natural geologically sourced leaching into ground and surface water. These sources pose an exposure risk above the United States Environmental Protection Agency (USEPA) standard (10ppb) to individuals whose food and water sources become contaminated. Arsenic exposure negatively impacts organ function and increases the risk for developing pathologies and cancer. Some of these effects of arsenic on various pathologies and cancer translate to potentially impacting normal cell function in processes such as wound healing. The current study utilized various in vitro techniques to elucidate arsenic's impacts on wound healing processes such as migration, proliferation, inflammation, steroid signaling, and tissue remodeling in cultured human neonatal dermal fibroblast (skin) cells (hDFn). Additionally, estrogen (17-beta estradiol) was used to potentially reverse the negative effects of arsenic on cellular processes. Estrogen has been shown to interact with arsenic and independently communicate with hDFn cells to help facilitate tissue repair during the wound healing process. Results demonstrated that hDFn cells exposed to concentrations of sodium arsenite ranging from 7.5ppb to 750ppb (environmentally relevant doses) decreased cellular proliferation, migration and metabolic activity compared to untreated controls. However, treatment with estrogen resulted in a mitigation of the negative effects of sodium arsenite, suggesting that estrogen may be interacting with arsenic while promoting in vitro cellular migration.

**MP153 Assessment of exposure to fluoride among young children and adults in low- and high- naturally fluoridated areas of Nigeria**

*O. Idowu, V.F. Zohoori, R.M. Duckworth, Teesside University / School of Health and Social Care; R.A. Valentine, Newcastle University / School of Dental Sciences*

Although topical fluoride (F) has proven to reduce dental caries, excessive systemic F ingestion leads to the development of dental fluorosis. Given the narrow gap between optimal and toxic F intake/exposure, considerable interest has been focused on intake, bioavailability, and pharmacokinetics of F. This study aimed to measure total daily fluoride intake (TDFI) from the diet and toothpaste ingestion in two age groups (4-5 and ≥20 years) living in low- and high- fluoridated areas (LFA and HFA, respectively) of Nigeria. Subsidiary aims were to measure F in 24-hour urine, plasma, saliva, hair and nails (fingernail and toenail). Parents were asked to complete a Food Frequency Questionnaire (FFQ) for themselves and their children, the F content of their diet was analysed to estimate the daily dietary fluoride intake (TDDFI), and toothpaste ingestion was estimated through a fluoride exposure questionnaire (FEQ). TDFI was calculated from TDDFI and toothpaste ingestion. Fluoride concentration in plasma and nails was measured by fluoride ion selective electrode (F-ISE) after overnight HMDS-facilitated diffusion. Urinary F excretion was determined after direct analysis by F-ISE. TDFI [mean(SD)] for children and adults respectively was 0.075(0.036) and 0.036(0.020) mg/kgbw/d in LFA (F concentration in drinking water ($F_W$) =0.04 mg/L) and 0.277(0.184) and 0.125(0.093) mg/kgbw/d in HFA ($F_W$=3.05 mg/L). In the HFA, TDFI was higher than the threshold of the tolerable upper intake level (UL: 0.1 mg/kgbw/d) for 80% of the children and 50% of adults, whereas in the LFA, 12.5% of the children exceeded the UL. There was a statistically significant difference ($p< 0.001$) between HFA and LFA for all the biological markers among both children and adults. Fluoride intake in the present study was mostly from the diet. Despite a low $F_W$ in the LFA, few of the children are at risk of dental fluorosis. However, most of the children living in the HFA are at risk to dental fluorosis. Therefore, the fluoride level of their biomarker samples will be useful in identifying children at risk of dental fluorosis.

**MP154 Nickel concentrations in blood from informal workers exposed and possible health effects in Colombian**

*K. Martinez Yanez; S. Mendoza-Caro, University of Cartagena / Environmental Chemistry Research Group, School of Exact and Natural Sciences; F.V. Murillo, Cartagena University / Exact and Natural Sciences School; A. Fortich-Revollo, University of Cartagena / School of Medicine; B. Johnson-Restrepo, University of Cartagena / Chemistry and the Environment Group / School of Exact and Natural Sciences*

In recent decades, the widespread use of heavy metals in modern life to improve our quality of life has caused many of these to come into contact with the environment either from natural sources or as a result of anthropogenic activities, causing various health problems, also to adverse health effects related to oxidative stress, DNA damage and possible carcinogenic; derived from its toxicity, non-biodegradability, bioaccumulation, biomagnification and persistence in the environment. In Colombia, many people earn their daily living doing informal work activities, this includes all those people who are engaged in small economic activities that take place outside the law; Therefore, in most cases, they do not receive any help in terms of professional training in environmental health, nor are they regulated by entities of public health, although in Colombia there is strict regulation on health in the workplace. The development of informal work activities without protection when cutting, welding, using, manipulating and melting some metals, is a direct exposure to Nickel (Ni), derived in activities of: welding, mechanics, carpentry, electricity, smelters, battery repair, electroplating among others. Nickel has not been recognized as an essential element in humans so it is not clear how nickel compounds are metabolized. For each individual the concentration of Ni in blood was determined by graphite furnace atomic absorption spectroscopy (GF-AAS), in a Thermo Fisher Scientic iCE Series 3500. The concentrations of Ni found in blood vary in values from non-detectable

(ND) to 14.3 µg/L Ni total. The average concentrations ± standard deviation (range) were in battery repairers: 4.5 ± 2.2 (1.78-7.91), fishermen: 4.2 ± 1.32 (1.8-9.76), electricians: 4.8 ± 1.5 (2.9-7.0), mechanics: 4.8 ± 2.1 (1.9-14.3), painter 5.1 ± 0.7 (4.2 -11, 7), welding: 3.8 ± 1.2 (1.9-8.0) and recyclers: 1.7 ± 1.6 (0-5.1). For to protect workers, OSHA has set an enforceable limit of 1.0 mg nickel/$m^3$ in workroom air to protect workers during an 8-hour shift over a 40-hour work week. We find the lack of reference values for nickel in blood, both at the general level and in the workplace, therefore, given the shortage of available data, the results that we contribute in our study they can be an important contribution. Acknowledgments: To Colciencias and the University of Cartagena for financing the project No. 110765843679.

### MP155 Dietary intake of trace elements in Catalonia (Spain): Temporal trends and health risks

*N. González, Universitat Rovira i Virgili / School of Medicine IISPV; M. Marquès, Universitat Rovira i Virgili / Chemical Engineering, IIPSV; M. Nadal, Universitat Rovira i Virgili / School of Medicine, IISPV; J.L. Domingo, Universitat Rovira i Virgili / Laboratory of Toxicology and Environmental Health*

Metals are natural components of the Earth's crust which can be widely present in different environmental matrices such as soil, water and air. These elements are environmentally persistent. Consequently, they can bioaccumulate in living organisms causing severe health effects. Therefore, human health risk assessments are required in order to protect human health. This study was aimed at estimating the current dietary intake of arsenic (As), cadmium (Cd), lead (Pb) and mercury (Hg), inorganic arsenic (InAs) and methylmercury (MeHg) through a total diet study (TDS). Temporal trends with respect to previous surveys performed in 2012, 2008, 2005 and 2000 were also determined. Food samples were purchased in 12 different cities of Catalonia. Food was selected among those most consumed according to ENALIA survey. For metal analyses, three composites were prepared for each food item, which in turnconsisted of 20 individual units. Regarding to human health risk, a probabilistic approach using Monte Carlo simulation was carried out. Dietary intake estimated for a male adult was 98.16, 2.58, 6.13, 6.38, 5.20 and 2.62 µg/day for As, InAs, Cd, Hg, MeHg and Pb, respectively. These values are below tolerable daily intake (TDI) set by international organisations. In addition, an important decrease compared with previous studies was noted for all elements. Notwithstanding, children population are at risk for cadmium and methylmercury because dietary intake values are above established security levels.

### MP157 Exposure assessment of equol and its chlorinated by-products

*K. Hu, Hangzhou CDC; L. Wu, Y. Zhou, S. Zhang, F. Zhao, Q. Kang, M. Ding, Peking University; W. An, Chinese Academy of Sciences; M. Yang, Chinese Academy of Sciences / Research Center for Eco-environmental Sciences; Q. Jin, Hangzhou CDC; J. Hu, Peking University*

This study simultaneously determined the concentration of equol and its chlorinated by-products in 1013 urine samples collected from 16 major cities across China using a sensitive dansylation LC-MS/MS method. Equol was widely detected in the urine samples with mean concentration of 33.7 ng/L (ND-312 ng/L), and chlorinated equols were for the first time detected in urine samples with concentrations of 8.0 ng/L (ND-1147 ng/L) for monochloro-equol and 0.39 ng/L (ND-144 ng/L) for dichloro-equol. The detection frequency in urine samples was 96% (970/1013) for equol, 21% (211/1013) for monochloro-equol, and 11% (111/1013) for dichloro-equol. The total concentrations of chlorinated equol in urine samples were significantly correlated with that of equol in urine samples ($p$=0.00005), suggesting they would be have common source. For well understanding the potential source, we further analyzed their occurrence in drinking water in China. The concentrations of equol and its chlorinated by-products in drinking water of 58 DWTPs across China were determined, we observed a lower level of equol in drinking water than that in urine samples (10.7 ng/L), and the mean concentrations of monochloro-equol (8.94 ng/L, ND-237 ng/L) and dichloro-equol (0.52 ng/L, ND-12.1 ng/L) in drinking water were similar to those in urine samples.

### MP158 Changes in Concentration of Per- and Polyfluorinated Substances in California Women's Serum

*S. Crispo Smith, California Environmental Protection Agency / Department of Toxic Substances Control; J. Park, California Environmental Protection Agency / Department of Toxic Substances Control / Environmental Chemistry Laboratory; T. Woodruff, R. Morello-Frosch, University of California San Francisco; L. Zhang, E. Harney, Public Health Institute*

Per- and polyfluorinated substances (PFASs) have been used in diverse industries from cosmetics and textiles to aerospace and automotive for several decades. Because of their chemical structure, PFASs are highly resistant to degradation and therefore bioaccumulate in food chains. In humans, PFASs bind to proteins in plasma and liver contributing to health problems such as cancer, ulcerative colitis, thyroid disease, high cholesterol, and pregnancy induced hypertension. Many studies have focused on maternal women's serum as pregnancy has a particular set of developmental and health risks associated with fetal development. Here, we will present trending PFAS data from both women and pregnant women's serum. Serum samples were measured for six perfluorinated carboxylic acids (PFCAs), three perfluorosulfonic acids (PFSAs), two alkylperfluorooctanesulfonamidoacetic acids (PFOSAAs), and one perfluorooctanesulfonamide (PFOSA) in human serum using an online SPE (Symbiosis Pro, Spark Holland)-HPLC-MS/MS (SCIEX QTRAP 4000 MS/MS) via a multiple reaction monitoring (MRM) method. Extending our previous work which showed downward trends in PFAS concentrations over time (1960s-2010), we report that most of the classic PFASs slowly but continuously decrease to present (2015-2016), likely due to phase-outs of long-chain perfluorochemicals and their precursors (polyfluoro) which occurred in 2010. This trend is consistent with NHANES data for the US general population since 1999/2000. However, we observed that detection frequencies of longer chain PFASs have increased over the years. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

### MP159 Temporal trend of polybrominated diphenyl ethers (PBDEs) in Northern California Pregnant Women

*J. Wang, Department of Toxic Substances Control; G. Yeh, Public Health Institute / California Department of Toxic Substances Control Environmental Chemistry Lab; S. Crispo Smith, California Environmental Protection Agency / Department of Toxic Substances Control; J. Park, California Environmental Protection Agency / Department of Toxic Substances Control / Environmental Chemistry Laboratory; T. Woodruff, University of California, San Francisco*

Polybrominated diphenyl ethers (PBDEs) were widely used as flame retardant. PBDEs have been found in a large variety of products including children's pajamas, furniture, building materials, and foam furniture. Technical mixtures pentaBDE and octaBDE were phased out in 2004, while decaBDE was voluntarily discontinued being used in 2013. PBDEs are a public health concern because they can disrupt the hormone system, especially of estrogen and thyroid hormones, and developmental exposures can increase risk of a number of adverse health outcomes, including effects on child brain development. Thus, previous studies focused on how phase-out of these technical mixtures has affected PBDE levels found in second trimester pregnant women and their developing fetus(s). Our objective in this study is to continue to follow up the temporal trend of major PBDEs since 2014. In addition, we investigate the PBDE distribution among fetal liver, placenta, and maternal blood serum. The serum samples were prepared via solid phase extraction utilizing RapidTrace® Solid Phase Extraction (SPE) Workstation, while the liver and placenta samples were analyzed for PBDEs using manual liquid-liquid extraction. Placenta samples were also freeze-dried prior to manual extraction. All extracts were quantitated using isotope dilution on a gas chromatograph coupled with high resolution mass spectrometer. Our earlier studies showed a significant drop in major PBDEs (sum of BDE-28, -47, -99, -100, and -153) between 2008-9 and 2011-12 (~ 40%), and then plateaued between the 2011-12 and 2014. Contrary to our earlier findings, the more recent study shows the levels of BDE-47 and BDE-99 slightly rising between 2014 and 2015 serum measurements and then continuing to show a downward trend in serum concentrations in 2016. The reason(s) for this episodic upward trend are being investigated, including studying the PBDE distribution in other matrices. Findings from this study will be added to collective biomonitoring data and help track the long-term behavior of these pollutants in the human body and environment. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

**MP160 Critical Review and Update of Relative Potency Values for Selected Carcinogenic PAHs**

*L.T. Haber, A.M. Pecquet (Willis), M. Vincent, University of Cincinnati / Department of Environmental Health; Y. Bonvalot, L. White, Health Canada / Environmental Health Programme*

In Canada and other countries, a relative potency approach has been widely used to estimate risks of polycyclic aromatic hydrocarbon (PAH)-containing mixtures in human health risk assessments. Generally, relative potency is defined as the ratio of the potency of the target PAH to the potency of the comparator chemical, generally benzo[a]pyrene (BaP). In 2010, the USEPA's IRIS Program released a draft update of their relative potency approach for PAH mixtures. The USEPA's Science Advisory Board (SAB) (2011a) recommended significant changes to any future update (USEPA, 2011b). Health Canada (HC) decided to explore updating their potency equivalent factors (PEFs) for 8 carcinogenic PAHs guided by the SAB advice for selecting studies and data based on *a priori* criteria. Methods include (1) updated literature search to select studies meeting *a priori* criteria (e.g., environmentally relevant exposure routes such as oral, dermal, etc.), (2) review of selected studies and extraction of data based on additional *a priori* criteria (e.g., studies with multiple doses of BaP and target PAH relative to tumor responses; reliable dose response data), (3) updated benchmark dose (BMD) modeling in support of the development of PEFs, (4) additional analyses due to limited available data meeting the *a priori* criteria, and (5) calculation of the PEFs based only on cancer bioassay data. None of the chemicals had a sufficient database for calculation of PEFs according to our *a priori* criteria, since no PAH had multiple PEFs from multiple studies, although one study met the criteria of multiple doses for BaP and the target PAH. The only study that was appropriate for PEF calculation was Habs et al. (1980), which evaluated several of the target PAHs of interest. This study was given a medium confidence rating relative to the rest of the database, but it may be considered low confidence in absolute terms, due to incomplete reporting and the potential for confounding from age-related tumours. Our analysis indicates that data appropriate for calculating PEFs for several carcinogenic PAHs are based almost exclusively on dermal studies, even though PEFs are most often used for oral exposure. Furthermore, the relevant data are typically based on old testing methods and lack needed dose-response data. New high quality studies that meet the SAB *a priori* criteria and with good dose response data are needed to evaluate whether the potency approach may be valid for carcinogenic PAHs.

**MP161 Evaluating Prop65 Exposure to Ethylene Oxide and 1,4-Dioxane in Personal Care Products**

*S.N. Vivanco, C. Kelly, P. Chowdhary, Wood Environment & Infrastructure Solutions, Inc*

Ethylene oxide and 1,4-dioxane have been found in consumer products as impurities in raw materials such as polyethylene glycol (PEG) and PEG derivatives. PEGs are created under a process known as ethoxylation, which can lead to residual ethylene oxide and generation of 1,4-dioxane. Ethylene oxide and 1,4-dioxane impurities are a concern in personal care products as they are recognized by several authoritative bodies as carcinogens, including California's Office of Environmental Health Hazard Assessment, which oversees implementation of the Safe Drinking Water and Toxic Enforcement Act of 1986 (also known as Prop65). Published literature suggests that ethylene oxide and 1,4-dioxane may be present in over 20% of consumer products such as shampoos, sunscreen, makeup, and moisturizers. Under Prop65, the safe harbor exposure limits for ethylene oxide and 1,4-dioxane are the no significant risk levels (NSRLs) of 2 and 30 micrograms per day, respectively. In order to evaluate Prop65 compliance, we have evaluated several types of PEG raw materials and analyzed samples of personal consumer products for ethylene oxide and 1,4-dioxane content. Our findings indicate that ethylene oxide is not present in the personal care products evaluated at detectable concentrations and 1,4-dioxane is detected in less than 6 percent of samples analyzed at concentrations below Prop65 exposure limits requiring warning notification. In general, purity standards for raw materials considered food additives are low enough to reduce exposure to impurities below Prop65 NSRLs.

**MP162 Cleaning product ingredient safety – How have ingredient listings for cleaning products changed over the past 5 years?**

*M. Ciarlo, EA Engineering, Science, and Technology, Inc., PBC; D. Ferrer, American Cleaning Institute; B. Greggs, Soleil Consulting, LLC*
